ABSTRACT—Tyrannosaurids were the apex predators of Late Cretaceous Laurasia, and their status as dominant carnivores has garnered considerable interest since their discovery, both in the popular and scientific realms. As a result, they are well studied and much is known of their anatomy, diversity, growth, and evolution. In contrast, little is known of the earliest stages of tyrannosaurid development. Tyrannosaurid eggs and embryos remain elusive, and juvenile specimens—although known—are rare. Perinatal tyrannosaurid bones and teeth from the Campanian–Maastrichtian of western North America provide the first window into this critical period of the life of a tyrannosaurid. An embryonic dentary (cf. *Daspletosaurus*) from the Two Medicine Formation of Montana, measuring just three centimetres long, already exhibits distinctive tyrannosaurine characters like a 'chin' and a deep Meckelian groove, and reveals the earliest stages of tooth development. When considered together with a remarkably large embryonic ungual from the Horseshoe Canyon Formation of Alberta, minimum hatchling size of tyrannosaurids can be roughly estimated. A perinatal premaxillary tooth from the Horseshoe Canyon Formation likely pertains to *Albertosaurus sarcophagus* and it shows small denticles on the carinae. This tooth shows that the hallmark characters that distinguish tyrannosaurids from other theropods were present early in life and raises questions about the ontogenetic variability of serrations in premaxillary teeth. Sedimentary and taphonomic similarities in the sites that produced the embryonic bones provide clues to the nesting habits of tyrannosaurids, and may help to refine the search image in the continued quest to discover baby tyrannosaurids.

Keywords: Tyrannosauridae; Embryo; Theropoda; Cretaceous; North America

Introduction

Tyrannosaurids were the apex predators of Late Cretaceous Laurasia, and were among the largest terrestrial predators ever (Persons et al. 2020). They have garnered considerable interest since their discovery (Osborn 1905), both in the popular and scientific realms. As a result, they are well studied and much is known of their anatomy, diversity, growth, and evolution (Brusatte et al. 2010). Recent discoveries have further elucidated the origin of their distinctive body plans (Xu et al. 2004, 2006, Lü et al. 2014, Nesbitt et al. 2019), sensory apparatus (Brusatte et al. 2016a, Carr et al. 2017, McKeown et al. 2020), and large body sizes (Erickson et al. 2004, Woodward et al. 2020). Osteohistological data have enabled detailed analyses of tyrannosaurid growth rate and life history (Erickson et al. 2004, Horner and Padian 2004, Woodward et al. 2020), showing that tyrannosaurids grew at high but inconsistent rates in the later stages of their lives. Recently discovered small tyrannosauroid taxa from the Early Cretaceous and early Late Cretaceous show that many of the characters once considered distinctive of larger tyrannosaurids evolved at smaller body sizes (Brusatte et al. 2016a, Nesbitt et al. 2019, Voris et al. 2019, Zanno et al. 2019). These may have enabled mid-sized tyrannosauroids to flourish in the Late Cretaceous after the extinction of allosauroids in North America (Zanno and Makovicky 2011, 2013).

In contrast, little is known of the earliest stages of tyrannosaurid development. Eggs and embryos remain elusive, only a handful of perinatal teeth have been described (Carpenter 1982), and juvenile specimens—although known—are rare (Carr 1999, Tsuihiji et al. 2011, Voris et al. 2019, Woodward et al. 2020). These immature specimens are essential because it is now recognized that the tyrannosaurid skeleton undergoes dramatic changes throughout ontogeny (Carr 1999, Currie 2003b, Carr 2020). Considerable debate in the past has stemmed from the

nature of these transitions and whether variation is best attributed to taxonomy or ontogeny. However, most recent analyses suggest that ontogeny can explain most of the changes observed (Carr 1999, Currie 2003b, Carr and Williamson 2004, Brusatte et al. 2016b, Woodward et al. 2020, Carr 2020). Information about the earliest stages of tyrannosaurid development is thus critical for understanding the nature and timing of these drastic changes. Such specimens are also important for the information they reveal about tyrannosaurid reproduction and development, a subject which has thus far been entirely conjectural. For example, based on a growth series of *Gorgosaurus libratus*, Russell (1970) speculated on the size and morphology of a hatchling tyrannosaurid, and this was refined with more information on allometry by Currie (2003b). These analyses suggested that tyrannosaur hatchlings would have been gracile, long-legged, and would have had skulls about 90 mm in length. Regardless, in the fifty years since Russell's hypothesis, no perinatal specimens have been uncovered that could test its accuracy.

Here perinatal tyrannosaurid bones are described from the Campanian–Maastrichtian of Alberta, Montana, and South Dakota. A perinatal tooth and an embryonic ungual from the Horseshoe Canyon Formation of Alberta are probably attributable to *Albertosaurus sarcophagus*. From the Two Medicine Formation of Montana, an embryonic dentary with teeth probably pertains to *Daspletosaurus horneri*. The morphology of each of these elements show that some of the distinctive features that distinguish tyrannosaurids from other Late Cretaceous theropods are already present early in ontogeny. Furthermore, they provide information on the size of tyrannosaurid hatchlings and some preliminary clues to the nesting habits of tyrannosaurids.

Materials and Methods

The specimens are described in the Results in light of the developmental and taxonomic conclusions reached in the Discussion. Thus, the justification of their identification follows their description. For in-depth justification of the identification of the material as tyrannosaurid, the reader is directed to the section entitled "Identity of the specimens" in the Discussion.

The material (Table 1) was excavated under the appropriate permits to GFF or JRH. UALVP 59599 and TMP 1996.005.0011 were surface collected from the Horseshoe Canyon Formation (HCF) in Treaty 7 Territory, the traditional home of the Kanai (Blood), Tsuu T'ina (Sacree), Siksika (Blackfoot), Piikani (Peigan), Nakoda (Stoney) and Métis First Nations (Fig. 1). TMP 1996.005.0011 was found by an amateur collector (C. Duszynski) in Horsethief Canyon northwest of Drumheller, Alberta (Fig. 1B), and no detailed locality information was recorded. The locality (FTS-2) where UALVP 59599 was surface collected in 2018 is near Morrin Bridge, Alberta (Fig. 1; Funston and Currie 2018a). Additional material from the site was found through screenwashing bulk sediment. An initial wash was done by D. Brinkman at the Royal Tyrrell Museum of Paleontology using a 0.2 cm square mesh and room temperature water. The remaining sediment was then bagged and systematically washed through increasingly fine square mesh trays (1.0, 0.8, 0.6, 0.2 cm mesh, in order) using room temperature water. No definitive tyrannosaurid specimens were recovered during screenwashing, although some small teeth may prove to be tyrannosaurid following future work. MOR 268 was collected in 1983 from the Egg

Gulch site (MOR locality no. TM-008) near Choteau, Montana, from the Two Medicine Formation. The site is on lands managed by the Montana Department of Natural Resources and Conservation. This area is the traditional home of the Niitsítpiis-stahkoii □□□□□□□ □□□□ (=Blackfoot/Niitsitapi □□□□□□), Ktunaxa ʔamakʔis, and Salish Kootenai (Flathead) peoples (Fig. 1). MOR 268 was encased in a dense mudrock and surface collected by B. Franz and W. Cancrow.

The FTS-2 locality was mapped using a DJI Mavic Air crewless aerial vehicle (UAV) fitted with a gimbal-stabilized camera with a 35-mm equivalent lens. An area of 0.6 km2 was mapped with 1080 photographs at an altitude of 100 m above the takeoff point over the course of six flights. This resulted in a maximum ground sampling distance of 30 mm/pixel, although most regions were sampled more precisely because the takeoff point was near the lowest point mapped. A height field was generated using Agisoft Metashape Standard version at medium-quality settings. Upon examination, small details including vegetation, stationary field crew, and tents can be resolved, indicating a high degree of precision. Future georeferencing using high-accuracy GPS coordinates may help to improve the accuracy of the map, but this was not possible for the present study. The contacts between the Horsethief and Morrin Members of the Horseshoe Canyon Formation (just above Coal Zone 9) and the modern sediment and outcrop were manually traced in MeshMixer to split the mesh. These meshes were recoloured and combined to produce the false colour image in Fig. 1.

MOR 268 and UALVP 59599 were photographed using a Nikon D7200 digital SLR camera with a Nikon AF-S Micro Nikkor 60 mm lens or a Nikon D7100 digital SLR camera with a Tamron SP Di Macro 90 mm lens. Photographs were processed in Adobe Photoshop CC, and where adjustments were made to exposure, contrast, or brightness, these were applied to the

whole image. Measurements were taken using digital calipers to an accuracy of 0.01 mm where possible or were measured in GeoMagic Design X from calibrated µ-CT data.

Synchrotron radiation µ-CT images of MOR 268 were taken at the Canadian Light Source facility on campus at the University of Saskatchewan in Saskatoon, Canada. The scan was done on a BMIT 05ID-2 beamline at 80 keV with a wiggler field of 1.8 T and two filters (3.3 mm aluminum, and 1.1 mm copper). Images were captured by a Hamamatsu ORCA Flash 4 detector used with an AA-60 beam monitor and a LuAG, 200 µm scintillator at an exposure of 45 ms. Three thousand images were collected over a 180° rotation of the specimen and reconstructed at a voxel size of 13 µm. Conventional µ-CT images of UALVP 59599 were taken using a Skyscan 1173 (Anderson Lab, University of Calgary). Scans were conducted at 80 kV and 100 µA with no filter. Four-hundred eighty-one Images were taken at a rotation step of 0.5° and reconstructed at a voxel size of 7.1 µm. Scans were visualized and hard tissue volumized using Amira software (v5.1).

Body size estimations for the embryonic material (MOR 268 and UALVP 59599) were generated using reduced major axis regression (RMA) based on an extensive dataset of tyrannosauroid specimens compiled by PJC (Table 2; Supplementary Material). The RMA method was chosen over the ordinary least squares method as it has been demonstrated to better account for symmetrical biological data (Smith 2009, Schott and Evans 2016), which is typical of allometric data. Additionally, in preliminary tests, RMA analyses consistently produced smaller confidence intervals than the ordinary least squares method and were therefore favoured. All regressions were run using PAST 4 software package (Hammer et al. 2001). Estimates of size were generated using the power function in Microsoft Excel 365, using the dependent variable (x value) and the regression equations ($y = mx + b$; Table 2), including trend (Table 3),

and 95% confidence interval (minimum and maximum) equations (Table 2). Non-tyrannosaurid tyrannosauroid specimens were included in the dataset only if their inclusion did not significantly change the regression estimates. The inclusion of non-tyrannosaurid tyrannosauroids, when appropriate, provided representation of otherwise missing size classes not yet known for tyrannosaurids. In particular, estimates for MOR 268 from regressions including tyrannosauroid data points were slightly lower and more reasonable given the morphology of the preserved part of the dentary and comparisons to juvenile tyrannosaurids (Supplementary Data).

Geological Settings and Localities

The geology and sedimentology of both the Horseshoe Canyon Formation and Two Medicine Formation are well studied. The Horseshoe Canyon Formation records a range of paralic nearshore to coastal plain paleoenvironments (Eberth and Braman 2012). The dinosaurian fauna is well known, consisting of alvarezsaurids, ankylosaurians, avians, caenagnathids, ceratopsians, dromaeosaurids, hadrosaurids, ornithomimids, pachycephalosaurids, thescelosaurids, troodontids, and tyrannosaurids (Eberth et al. 2013). Sediments in the Horsethief Member of the Horseshoe Canyon Formation, where the Albertan specimens were found, were deposited during a wet and warm climatic interval, leading to abundant coal formation (Eberth and Braman 2012). Two significant coal seams crop out in the field area (Fig. 1E, F) and allow the stratigraphy of the sites to be tightly constrained. Each of the sites producing the material described herein are between Coal Zones 8 and 9 and can be temporally constrained to a range of 71.832 (± 0.044) to 71.5 (± 0.1) Ma (Eberth and Kamo 2019). Whether these sites are latest Campanian or earliest Maastrichtian is unclear: the global boundary is set within magnetochron

177 32n.2n (Ogg and Hinnov 2012), but in the Red Deer River Valley, this is divided into three
178 subchrons with intervening reversals (Eberth and Kamo 2019). The FTS-2 bed, described briefly
179 by Funston and Currie (2018a), immediately underlies Coal Zone 9 (Fig. 1F), which marks the
180 boundary with the overlying Morrin Member. The environments of the Morrin Member were
181 subject to cooler, drier climates than the Horsethief Member, resulting in more extensive
182 pedogenesis and less coal formation (Eberth and Braman 2012). The FTS-2 bed is a laterally
183 restricted greenish-grey silty mudstone with massive bedding. A single sandy lens interrupts the
184 massive bedding near the base; this horizon is locally sideritized but is not more fossiliferous
185 than the rest of the bed. The FTS-2 bed is lenticular, tapering in thickness to the south and
186 presumably the north, although this latter area has been truncated by a slump (Fig. 1E, F). It is an
187 overbank deposit, but it is distinctive compared to other interfluve deposits in the Horsethief
188 Member in its great thickness, lenticular shape, and greenish colour. Furthermore, fossils at FTS-
189 2 are not concentrated in a single horizon, rather, they are evenly distributed throughout the bed
190 and are accumulated as a deflation lag. At least two other microsites in the Horsethief Member
191 have similar lithology to FTS-2, and all of these are stratigraphically equivalent, occurring just
192 below Coal Zone 9. One of these sites, L2000, was described by Ryan et al. (1998). Each of
193 these three sites preserves an abundance of troodontid teeth, and both FTS-2 and L2000 have
194 produced relatively abundant isolated bones of embryonic dinosaurs (Ryan et al. 1998). The
195 FTS-2 assemblage is unusual in its abundance of anurans and the preservation of eggshell
196 (Funston and Currie 2018a). The distinctive faunal assemblages and lithologies of these beds
197 suggests that they represent a distinct paleoenvironment, which was probably less fluvially
198 influenced and more upland than other overbank deposits in the Horsethief Member. Possible
199 paleoenvironments could include a marginal pond or wetland settings among other options (Ryan

et al. 1998), but more detailed sedimentological work is required to confirm any of these possibilities.

The Two Medicine Formation preserves a wide range of paleoenvironments, which are generally more arid than those of the Horseshoe Canyon Formation (DeMar et al. 2017). The dinosaurian fauna is similar to that of the Horseshoe Canyon Formation, and ankylosaurians (Arbour and Currie 2013), avians (Atterholt et al. 2018), caenagnathids (Varricchio 2001), ceratopsians (Sampson 1995, Wilson et al. 2020), dromaeosaurids (Burnham et al. 2000), hadrosaurids (Horner 1982, Horner et al. 2000), thescelosaurids (Horner and Weishampel 1988), troodontids (Varricchio 1993), and tyrannosaurids (Carr et al. 2017) have been recovered. Little work has focused on the particular locality that produced MOR 268 (Egg Gulch; TM-008), but its lithology is generally similar to the nearby (~1 km), better-studied Egg Mountain locality (TM-006; Lorenz and Gavin 1984). The sediments at Egg Gulch are mudstones associated with anastomosing and braided streams. MOR 268 was collected from a sequence of alternating mudstones and caliche nodules, which likely represent soil horizons. Like the Egg Mountain locality, the paleoenvironment of Egg Gulch had minimal marine influence, evinced by a terrestrial fauna with abundant *Maiasaura* nests and eggs.

Systematic Palaeontology

Theropoda Marsh 1881

Tyrannosauridae Osborn 1905

cf. *Albertosaurus sarcophagus* Osborn 1905

Description:

UALVP 59599—A small pedal ungual (Fig. 2; 10 mm in length) was recovered from the FTS-2 locality in the Horsethief Member of the Horseshoe Canyon Formation near Morrin, Alberta. As outlined in more detail in the discussion (see Discussion), the specimen can be tentatively identified as tyrannosaurid by its distally tapering shape, its relatively tall proximal height, the absence of a proximal constriction, and its large size at an embryonic phase of development. The surface of the ungual is highly porous, consistent with embryonic bones in other dinosaurs (Horner and Currie 1994, Kundrát et al. 2007, Reisz et al. 2010). The ungual is triangular in cross-section with deep longitudinal vascular grooves, and it tapers to a blunt point distally (Fig. 2). The proximal articular surface of the ungual is not yet developed, and instead there is a deep conical pit (Fig. 3). There is no clearly defined flexor tuber on the proximal plantar surface, and instead a shallow concavity extends mediolaterally. The plantar surface of the ungual is slightly convex in proximal view (Fig. 2F) but appears approximately flat in lateral view (Fig. 2A, B). The ungual is transversely broad across its ventral surface, but above the vascular grooves it is transversely compressed (Fig. 2E, F). Asymmetry in the height of the lateral and medial vascular grooves above the plantar surface of the ungual (Fig. 2E) allows the ungual to be oriented: the lateral vascular groove is dorsal to the medial vascular groove in theropods (pers. obs.). Furthermore, the ungual is not symmetrical about its midline, rather, the vertical axis of the ungual is laterally inclined, instead of being perpendicular to the plantar surface (Fig. 2E, F). Similarly, the proximal face of the ungual is anteromedially inclined in dorsal and ventral view (Fig. 2C, D), and thus the tip is deflected medially with respect to the proximal end. Unguals II-3 and IV-5 are asymmetrical in tyrannosaurids, as in most other theropods, and typically each of these are curved away from digit III (Lambe 1917). Thus, ungual II-3 curves medially, whereas ungual IV-5 curves laterally. The lateral inclination of the

246 vertical axis and the medial deflection of the tip of the ungual suggest that this is a left ungual II-
247 3.

248 *TMP 1996.005.0011*—A small, rooted premaxillary tooth (Fig. 4) was recovered in the
249 Horseshoe Canyon Formation exposed at Horsethief Canyon, northwest of the town of
250 Drumheller, AB. The tooth can be identified as tyrannosauroid by its incisiform morphology
251 with the carinae aligned on the lingual surface of the tooth, producing a distinctive D-shaped
252 cross-section considered synapomorphic of Tyrannosauroidea (Brusatte and Carr 2016). The
253 entire tooth is 16 mm tall, of which the crown forms about half (8.5 mm crown height; Fig. 4A–
254 D). The root is oval in cross-section and has a slightly swollen appearance, tapering
255 buccolingually towards its base and transversely towards the crown. (Fig. 4B, D) The latter taper
256 towards the crown results in a subtle transverse constriction at the base of the crown. The crown
257 is minimally recurved and the carinae are positioned on the lingual edges of the mesial and distal
258 sides of the tooth, resulting in a D-shaped cross-section. This produces the distinctive incisiform
259 morphology typical of adult tyrannosaurid premaxillary teeth (Currie et al. 1990, Currie 2003a,
260 Brusatte and Carr 2016). The carinae are serrated and each denticle is small, rounded, and
261 protrudes only minimally from the carina. On the lingual surface of the tooth, a midline
262 longitudinal ridge is separated from each carina by a shallow groove (Fig. 4B, D). The mesial
263 and distal edges of the tooth differ in curvature: whereas one is relatively straight, the other is
264 curved so that the apex of the tooth is off-centre (Fig. 4B, D). Comparison to other
265 tyrannosaurids with *in situ* premaxillary teeth (Lambe 1917, Brochu 2003, Currie 2003a, Tsuihiji
266 et al. 2011, Hanai and Tsuihiji 2019) suggests that this is a feature of the first or second
267 premaxillary teeth and that the curved carina is the mesial one. Therefore, this tooth likely
268 represents the first or second right premaxillary tooth of a small individual.

cf. *Daspletosaurus* Russell 1970

cf. *Daspletosaurus horneri* Carr et al. 2017

Description:

MOR 268—MOR 268 is a partial left dentary with eight teeth (Figs. 5–7). It is preserved as a part and counterpart (Fig. 5), with the larger part containing most of the dentary, and the counterpart preserving parts of the teeth and the lingual wall of the dentary where it forms the lingual walls of the alveoli. The specimen can be identified as a tyrannosauroid on the basis of one synapomorphy, a deeply incised Meckelian groove, and as a tyrannosaurid by two synapomorphies: the presence of a chin below the fourth alveolus and the smaller size of the anterior two alveoli (see Discussion). The dentary is elongate (29 mm as preserved) relative to its dorsoventral depth (minimum height 3.2 mm) and remarkably straight in ventral view (Fig. 6D). The dorsal edge of the dentary is gently convex at its anterior end, but concave posterior to the fifth alveolus (Fig. 6C). The anterior and ventral margins of the dentary meet at a distinctive 'chin' (Figs. 5A,C,E; 6A, C, E, F), as in other tyrannosaurids (Currie 2003a, Carr and Williamson 2004, Brusatte and Carr 2016, Mallon et al. 2020) but unlike troodontids, dromaeosaurids, or other Late Cretaceous theropods. The lateral surface of the dentary (Fig. 6C, F) is pierced by numerous foramina, which are arranged into three main rows. The dorsal (or alveolar) row comprises several large, anterodorsally opening foramina anteriorly, but the foramina become smaller posteriorly and are set into a groove. Like in other tyrannosaurids, this groove curves gently ventrally, so that it is furthest from the dorsal edge of the dentary at the seventh alveolus. A middle row of foramina extends posterior to the sixth alveolus, descending

posteriorly to merge with the ventral row of foramina towards the posterior end of the preserved dentary. Like the ventral row, foramina in the middle row become shallower and more anteroposteriorly extended toward the posterior end of the dentary. The middle row of foramina is not described on most tyrannosaurid jaws, but it is present in many specimens, including juvenile *Gorgosaurus libratus* (TMP 1994.012.0155) and *Daspletosaurus horneri* (MOR 553S 7-19-0-97) as well as *Albertosaurus sarcophagus* (TMP 2003.045.0084), *Alioramus altai* (IGM 100/1844), *Daspletosaurus torosus* (CMN 8506), and *Tyrannosaurus rex* (BMRP 2002.4.1) (T. Carr, pers. comm. 2020). As in other tyrannosaurids, the ventral row of foramina in MOR 268 parallels the anterior and ventral edges of the dentary (Fig. 6D). The medial surface of the dentary (Fig. 6A, E) is deeply incised by the Meckelian groove, which extends longitudinally just below the dorsoventral midpoint of the dentary. The Meckelian groove ends anteriorly in a deep fossa underlying the fourth alveolus, directly dorsal to the ventral 'chin' of the dentary (Figs. 5A, C, E; 6A, E). Posteroventral to this pocket, there is a large foramen (Fig. 6A). The lingual wall of the dentary above the Meckelian groove is flat and straplike in appearance (Fig. 6A, E). Anterior to the termination of the Meckelian groove, the contact surface for the opposing dentary is relatively smooth and flat, although there is faint rugosity near the ventral edge (Fig. 6E). In adult tyrannosaurids, this region becomes extensively rugose. Posteriorly, the dorsal part of the dentary narrows transversely and becomes platelike, although this region is mostly missing (Fig. 6B). The ventral edge of the dentary is rounded and more consistent in transverse thickness throughout its length (Fig. 6D). Towards the posterior third of the preserved portion, the thickened ventral edge tapers dorsoventrally, and in this area, there is a distinct facet for the insertion of the splenial (Fig. 6A). Synchrotron radiation μ-CT images show that in this region, the Meckelian canal merges with an internal ventral canal, and together these exit the dentary

315 through an anteroposteriorly elongate foramen on the lateral surface of the dentary (Fig. 6C). The
316 posterior edge of the dentary is mostly broken, but there is a small, curved portion that appears
317 undamaged.

318 Portions of ten alveoli are preserved, although the anterior two are badly damaged (Fig.
319 6E). The second alveolus is much smaller than the more posterior alveoli, as is the case in adult
320 tyrannosaurids (Currie 2003a, Loewen et al. 2013, Fiorillo and Tykoski 2014, Brusatte and Carr
321 2016, Hendrickx et al. 2019). The second alveolus is 0.7 mm in length, which is 56% of the
322 mean length of the third to tenth alveoli (1.25 mm; Table 1). Each alveolus is roughly elliptical
323 in occlusal view, with a longer anteroposterior axis than transverse axis (Fig. 6E). The mesial
324 and distal edges of the posterior alveoli (the seventh through tenth) are slightly flattened,
325 resulting in a 'boxy' appearance in occlusal view (Fig. 6E). This morphology was described by
326 Chiarenza et al. (2020) as distinguishing tyrannosauroids from dromaeosaurids. Borders between
327 the alveoli are demarcated by ridges projecting medially from the lateral wall of the dentary, and
328 these are met by separate ossifications on the medial side of the alveoli, representing the
329 interdental plates (Fig. 6E). These interdental plates are especially well-developed anteriorly and
330 between alveoli nine and ten but are less well-developed between the seventh to ninth alveoli.
331 This discrepancy is unsurprising, however, considering that interdental plates originate from
332 alveolar bone deposited during tooth development (LeBlanc et al. 2017) and the seventh alveolus
333 has only a small bell-shaped tooth. In contrast, the ninth alveolus lacks any evidence of a tooth
334 (Fig. 7B, C). Like in other tyrannosaurids, interdental plates are offset by a step from the lingual
335 wall of the dentary. Synchrotron radiation μ-CT images show that they are composed of highly
336 porous, disorganized bone, that contrasts with the denser bone of the lingual wall of the dentary.

Eight teeth are preserved in different stages of development (Fig. 7). The smallest teeth, in the second and seventh alveoli, are conical and hollow. This corresponds to the early crown phase of tooth development. Each of these teeth lie in the anterior portion of the alveolus (Fig. 7B) and would presumably have moved posteriorly as they developed. The sixth and eighth teeth are apparently in a slightly later stage of development, suggested by crowns that are transversely narrow but without well-developed roots. The fifth tooth is the largest but extends only partly above the labial wall of the dentary. This tooth is transversely wider than the more posterior teeth, and more closely resembles the typical robust morphology of adult tyrannosaurid teeth, suggesting it was a functional tooth. Tooth ten also protrudes slightly above the dorsal margin of the alveolus, but its root is less well-developed than the fifth tooth (Fig. 7C). Tooth eight is somewhat unusual in that its apicobasal axis is oriented posterodorsally, whereas the apicobasal axes of all the other preserved teeth are oriented anterodorsally (Fig. 7C).

Two teeth are present in the fourth alveolus, arranged labiolingually (Fig. 7C, D). The labial tooth is the larger of the two, but it is mesiodistally narrower than the other large teeth in the jaw. It has a long root that extends to the base of the alveolus, but it lacks a well-developed layer of enamel on the crown (Fig. 7D). Specifically, whereas the dentino-enamel junction is clearly visible in the other teeth (Fig. 7E), no such distinction can be identified in this tooth (Fig. 7D). If enamel is present, it is distributed as discontinuous spicules throughout the height of the crown. However, the identity of these spicules is unclear: although they are denser than the surrounding tooth tissue, they could be heterogeneity in the density of the dentine, or they could be another tissue, like cementum. In any case, the absence of an extensive enamel sheath on the crown is similar to t1 (null) generation teeth in alligators, geckos, and other dinosaurs: these are small, non-functional teeth where enamel is less well developed (Westergaard and Ferguson

1990, Zahradnicek et al. 2012, Chapelle et al. 2020, Reisz et al. 2020). The smaller tooth in the fourth alveolus encroaches on the root of the larger tooth, but there is no evidence of root resorption in the μ-CT images (Fig. 7D). This arrangement is similar to that recently described in the t1 and t2 tooth generations of embryonic *Lufengosaurus* (Reisz et al. 2020). As in *Lufengosaurus*, there is no intervening mineralized tissue between the two teeth in the alveolus (Fig. 7D). Combined with its unusual morphology, this unusual arrangement suggests that the narrower, labially-positioned tooth in the fourth alveolus is from the t1 generation. However, the lingual t2 tooth is in an earlier stage of development than those described for *Lufengosaurus*.

Synchrotron radiation μ-CT images clearly show the dentino-enamel junction on the larger teeth (Fig. 7E), which indicates that enamel is present on the outer surfaces of the teeth. However, denticles are apparently absent from all of the teeth, as is the case in embryonic troodontids (Varricchio et al. 2002, 2018) and megalosauroids (Araújo et al. 2013).

Discussion

Developmental stages of the specimens:

The fragmentary and isolated nature of the specimens makes it difficult to determine their development stages with certainty. Nonetheless, some indications can be found in the embryology of extant diapsids, as well as the developmental stages inferred for fossil perinates of other dinosaurs.

Several lines of evidence indicate that the small ungual (UALVP 59599; Figs. 2, 3) is from a perinatal individual, most likely an embryo. The highly porous bone (Fig. 3E) and the absence of a distinct proximal articular surface (Figs. 2F; 3C, D) are evidence of an early

383 developmental stage for this bone. The latter feature conforms with observations in extant
384 tetrapods that unguals ossify from the distal end towards the proximal end (Sharpey-Schafer and
385 Dixey 1880, Dixey 1881, Fröbisch 2008). The deep conical depression on the proximal end (Fig.
386 3B) suggests that this region of the ungual remained uncalcified. Thus, ossification of the
387 element had begun but was not yet complete. Ossification of the terminal phalanges begins
388 relatively early in embryonic development in a wide range of tetrapods (Fröbisch 2008),
389 including birds (Maxwell 2008a, 2008b, 2009, Maxwell and Harrison 2008), turtles (Rieppel
390 1993b, Werneburg et al. 2009), squamates (Rieppel 1992, 1993a, 1994, Gregorovičová et al.
391 2012), crocodylians (Müller and Alberch 1990, Rieppel 1993c, Vieira et al. 2016, Gregorovičová
392 et al. 2018), and mammals (Gray et al. 1957, O'Rahilly et al. 1960, Han et al. 2008), which
393 suggests this pattern is conserved within Tetrapoda. The onset of ungual ossification is always
394 during fetal development, and the pedal phalanges are typically well-developed before hatching,
395 although the onset of their ossification relative to other phalanges varies (Maxwell et al. 2010).
396 This pattern appears to hold for embryonic dinosaurs preserved *in ovo*: well-ossified phalanges,
397 including unguals, similar to adult morphology are known in ceratopsians (Erickson et al. 2017,
398 Norell et al. 2020), hadrosaurids (Horner and Currie 1994), oviraptorosaurs (Weishampel et al.
399 2008, Wang et al. 2016), sauropodomorphs (Reisz et al. 2010, 2013), and therizinosaurids
400 (Kundrát et al. 2007). Hatchling or perinatal ceratopsians (Meng et al. 2004, Fastovsky et al.
401 2011, Hone et al. 2014), hadrosaurids (Horner and Currie 1994, Dewaele et al. 2015, Prieto-
402 Marquez and Guenther 2018), and oviraptorosaurs (Lü et al. 2013) all have well-developed
403 unguals with complete proximal articular surfaces, which further supports the notion that unguals
404 are well-developed by the time of hatching. Together, these lines of evidence constrain the age of
405 UALVP 59599 as sometime in late fetal development. However, narrowing this range is

406 difficult. Balanoff and Rowe (2007) described an *in ovo* embryo of the Elephant Bird *Aepyornis*,
407 which they estimated at approximately 80–90% through incubation. They describe two pedal
408 unguals that are remarkably similar in development to UALVP 59599, in being well ossified but
409 retaining a deep depression for the proximal cartilage cone (Balanoff and Rowe 2007). Thus, we
410 tentatively interpret UALVP 59599 as representing a similar stage of development, though we
411 note that more investigation is needed into the usefulness of unguals for determining
412 developmental stages in archosaur embryos.

413 The small premaxillary tooth (Fig. 4) exhibits the distinctive morphology of adult
414 tyrannosaurid premaxillary teeth, but determining its developmental stage is difficult. The
415 premaxillary crowns of MPC-D 107/7, a juvenile *Tarbosaurus bataar* from the Nemegt
416 Formation of Mongolia, are each about 10 mm in height, compared to a skull length of 290 mm
417 and a femoral length of 303 mm. This would suggest a skull length of ~250 mm and a femoral
418 length of ~260 mm for the individual represented by TMP 1996.005.0011 (crown height 8.5
419 mm). However, these predictions assume both isometry and equal proportions of these elements
420 between taxa at this growth stage, neither of which can be rigorously tested with known material.
421 Regardless, considering that the histology of MPC-D 107/7 shows that it is a juvenile
422 approximately three years old (Tsuihiji et al. 2011), it is unlikely that TMP 1996.005.0011
423 represents a hatchling individual. Rather, it was likely a nestling or young juvenile. *Tarbosaurus*
424 *bataar* grew to a larger adult size than *Albertosaurus sarcophagus*, but it is not clear whether
425 young individuals of the same age of each taxon would have differed considerably in size. This
426 creates further uncertainty in the developmental stages of the individual represented by TMP
427 1996.005.0011, but it was clearly a young juvenile. However, some evidence suggests that
428 variation in adult body size in tyrannosaurids is the result of differing growth rates during the

interval of maximum growth (Erickson et al. 2004). This suggests that young tyrannosaurids like MPC-D 107/7 and TMP 1996.005.0011 might have been closer in body size at equivalent ages during early ontogeny, with taxonomic differences in body size only manifesting later in life. In light of the uncertainty in the developmental stage of the tooth, TMP 1996.005.0011 is best considered a young juvenile of an indeterminate age.

The developmental stage of MOR 268 (Figs. 5–7) can be constrained with certainty to the embryonic phase of development, but its position within this phase is less clear. The unusual tooth in the fourth alveolus of MOR 268 shows all of the hallmark features of t1 teeth: it is narrower mesiodistally than other teeth (Fig. 7C), it has less well-developed enamel than the other teeth, its replacement tooth is arranged lingually (Fig. 7D), and there is no evidence of root resorption (Chapelle et al. 2020, Reisz et al. 2020). The presence of a t1 tooth is strong evidence for the embryonic status of MOR 268. Although they are variably present in diapsids, t1 teeth are invariably shed or resorbed during the incubation period, and frequently two or more subsequent generations of functional teeth have erupted (Zahradnicek et al. 2012, Chapelle et al. 2020, Reisz et al. 2020). However, the timing of development of t1 teeth and their replacement by functional teeth is poorly understood. Data from geckos suggests the earliest they are present is 23% through incubation, and they form half of the dentition at approximately two-thirds of the way through pre-hatching development (Zahradnicek et al. 2012, Chapelle et al. 2020). After this point, they are replaced by the functional teeth (Reisz et al. 2020), as appears to be the case in MOR 268. The timing of the presence of functional teeth in development varies in extant diapsids, varying from as early as 42% of development in crocodilians (Ferguson 1985) to later than 50% in squamates (Jackson 2002, Boughner et al. 2007, Noro et al. 2009), to as late as 66% in birds when induced artificially (Harris et al. 2006). The presence of multiple functional teeth

in the jaw (Fig. 7C) therefore suggests a developmental stage close to or, more likely, greater than 50% in MOR 268. However, further work on t1 generation teeth in extant diapsids is necessary to refine this estimate.

The degree of ossification of the dentary may also provide some clues to further constrain the developmental window of MOR 268. Under the criteria of Chapelle et al. (2020), the dentary of MOR 268 can be scored as stage 3: closely resembling the juvenile shape, short of complete expansion. This is supported by the strong resemblance of MOR 268 to juvenile tyrannosaurids (Fig. 8) like IVPP V4878 (*"Shanshanosaurus huoyanshanensis"*), MOR 553S 7-19-0-97 (*Daspletosaurus horneri*), MPC-D 107/7 (*Tarbosaurus bataar*), TMP 1994.012.0155 (*Gorgosaurus libratus*), and TMP 1994.143.0001 (*Gorgosaurus libratus*). In their extant dataset, the earliest that dentaries were coded at stage 3 was 52% through pre-hatching development (Chapelle et al. 2020). This tentatively suggests that MOR 268 was in the latter half of fetal development, which is also supported by the presence of functional teeth in tandem with a t1 generation tooth.

That both dental and osteological lines of evidence coincide strongly suggests that MOR 268 is best interpreted as an embryo in the second half of fetal development. However, it is clear that MOR 268 was still some time from hatching. None of the functional teeth have well-developed roots (Fig. 7C), and at least four tooth positions have not yet progressed past the earliest crown development phase. Indeed, at least two of the alveoli (the third and ninth) lack any evidence of teeth at all (Fig. 7B). Considering that a full complement of functional teeth are developed by hatching in extant diapsids and other dinosaurs (Oliver W. M. Rauhut and Regina Fechner 2005, Araújo et al. 2013, Erickson et al. 2017, Reisz et al. 2020), this suggests that MOR 268 was closer to the middle stages of fetal development than the final stages.

Identity of the specimens:

UALVP 59599—The combination of the large size and embryonic developmental stage of UALVP 59599 eliminates squamates, choristodires, crocodylomorphs, and mammals as possible candidates for its identity. Each of these taxa are present in the HCF, but are represented by relatively small-bodied taxa compared to other geological formations from which they are known (Gao and Fox 1996, Wu et al. 1996, Brinkman 2003). Among non-dinosaurian reptiles in the HCF, only the nanhsiungchelyid *Basilemys morrinensis* (Mallon and Brinkman 2018), which is relatively rare in the HCF (Brinkman 2003, Brinkman and Eberth 2006), would have been large enough to have had unguals of this size at a young developmental stage. However, UALVP 59599 is dissimilar to the unguals of *Basilemys* in that the former is tall at the proximal end, triangular in cross-section, and has deep longitudinal vascular grooves. Unguals in *Basilemys* and other nanhsiungchelyids are dorsoventrally flattened, oval in cross section, and have shallow vascular grooves. Instead, the size and morphology of the ungual are most consistent with a dinosaurian identity. Among non-avian dinosaurs, perinatal unguals are known for ceratopsians (Fastovsky et al. 2011, Hone et al. 2014, Erickson et al. 2017, Norell et al. 2020), hadrosaurids (Horner and Currie 1994, Dewaele et al. 2015, Prieto-Marquez and Guenther 2018), oviraptorosaurs (Weishampel et al. 2008), therizinosaurids (Kundrát et al. 2007), and sauropods (Schwarz et al. 2007, Reisz et al. 2010, 2013). The tapering tip of the ungual argues against a ceratopsian or hadrosaur identity, as even embryonic ornithischian unguals exhibit the broad, 'hooved' morphology typical of adult unguals (Horner and Currie 1994, Erickson et al. 2017). Sauropods have tapered unguals, but are not known from the Horseshoe Canyon Formation,

498 despite more than a century of intense collecting (Eberth et al. 2013). Thus, the most likely
499 option is that UALVP 59599 pertains to a theropod, with which its morphology is consistent.
500 However, it differs from most theropods in that it is not curved. This appears to be true of the
501 pedal unguals of other embryonic theropods as well (Kundrát et al. 2007, Weishampel et al.
502 2008), and thus ungual curvature may have increased through ontogeny. Among theropods, the
503 pedal ungual is most similar in shape to those of avimimids (Funston et al. 2019), ornithomimids
504 (Longrich 2008), and tyrannosaurids (Brochu 2003, Mallon et al. 2020). The presence of
505 avimimids in North America is no longer supported (Funston et al. 2018), but UALVP 59599 is
506 comparable in size to unguals of adult avimimids, and is therefore unlikely to pertain to an
507 avimimid regardless. UALVP 59599 lacks the proximal constriction and flexor fossa of the
508 plantar surface observed in the pedal unguals of ornithomimids (Longrich 2008). Considering the
509 early developmental stage of UALVP 59599 (see above), its size (10 mm in length) is
510 remarkable, which helps to refine its possible identity. UALVP 59599 is more than double the
511 length of the pedal unguals in embryonic therizinosaurids (Kundrát et al. 2007) and
512 oviraptorosaurs (Weishampel et al. 2008), and is comparable in size to young sauropods
513 (Schwarz et al. 2007) and nestling hadrosaurids (Horner and Currie 1994, Prieto-Marquez and
514 Guenther 2018). Two ornithomimids are known from the Horseshoe Canyon Formation:
515 *Dromiceiomimus brevitertius* (Macdonald and Currie 2019), and *Ornithomimus edmontonicus*
516 (Russell 1972). Both taxa are relatively small-bodied and are unlikely to have had larger
517 embryos than therizinosaurs and oviraptorosaurs. Furthermore, as mentioned previously,
518 UALVP 59599 differs from the unguals of ornithomimids in the absence of a proximal
519 constriction, which forms a distinctive ‘arrowhead’ shape in ventral view. Caenagnathids are also
520 known from the HCF (Sues 1997, Funston and Currie 2016, 2018b), but these were similar in

size to ornithomimids and are likewise unlikely to have had such large embryos. Tyrannosaurids are the largest theropods in the Horseshoe Canyon Formation, and the relatively large size of the ungual combined with its early developmental stage therefore strongly suggests it represents an embryonic tyrannosaurid. Considering that only a single tyrannosaurid taxon, *Albertosaurus sarcophagus*, is currently known from the Horseshoe Canyon Formation (Carr 2010, Mallon et al. 2020), it is likely that UALVP 59599 pertains to this taxon, but it cannot be definitively referred. Beyond its size, some morphological features of the ungual further support its identification as a tyrannosaurid, although it is unknown how theropod unguals change throughout ontogeny. The ventral flatness of UALVP 59599 is reminiscent of small-bodied tyrannosaurids, the unguals of which are less recurved than other theropods (UALVP 49500; MPC-D 107/7; Mallon et al. 2020). Also, the distal tip of the ungual is blunt, which is similar to tyrannosaurids to the exclusion of most other theropods (Holtz 2004). Finally, the proportions of UALVP 59599 give it a stout appearance, as its proximal height and maximum transverse width are large relative to its total length. This is similar to subadult and adult tyrannosaurids (Lambe 1917, Brochu 2003, Mallon et al. 2020), but contrasts most other theropods, including caenagnathids, ornithomimids, and troodontids, in which unguals II-3 are longer and more slender (Sternberg 1932, McFeeters et al. 2018). While none of these features indicate with certainty that UALVP 59599 is referable to Tyrannosauridae, they show that UALVP 59599 is consistent with the morphology of other tyrannosaurid unguals.

TMP 1994.005.0011—The small premaxillary tooth (TMP 1996.005.0011) can be confidently identified as tyrannosaurid based on several features, but its identity within the group is less clear. Tyrannosaurid premaxillary teeth are distinctive in their incisiform shape, with the

544 mesial and distal carinae aligned on the lingual surface of the tooth (Currie et al. 1990, Currie
545 2003a). This produces a characteristic D-shaped cross-section that is unique among theropods
546 (Currie et al. 1990, Holtz 1994). Indeed, this unique character is considered a synapomorphy of
547 Tyrannosauroidea (or a more exclusive clade) by nearly all phylogenetic analyses including
548 dental characters (Brusatte et al. 2010, Loewen et al. 2013, Brusatte and Carr 2016, Hendrickx et
549 al. 2019). Whereas the premaxillary teeth of other theropods are modified compared to the more
550 distal maxillary and dentary teeth (Currie 1987, Currie et al. 1990, Currie and Evans 2019), they
551 do not approach the incisiform condition of tyrannosaurids. Most tyrannosaurid premaxillary
552 teeth, including the one described here, are further characterized by a longitudinal ridge on the
553 lingual surface of the tooth, separated from the carinae by shallow longitudinal grooves. This
554 feature was initially regarded as unique to *"Aublysodon"* (Molnar and Carpenter 1989), but is
555 now considered synapomorphic of the group (Carr and Williamson 2004, Brusatte et al. 2010,
556 Loewen et al. 2013, Brusatte and Carr 2016). Like UALVP 59599, TMP 1996.005.0011 is likely
557 referable to *Albertosaurus sarcophagus* because no other tyrannosaurids are known from the
558 Horseshoe Canyon Formation, but it lacks any characters to allow a definitive referral. It is
559 noteworthy that despite the small size of this tooth, it possesses incipient, poorly formed
560 denticles, in contrast to small tyrannosaurid premaxillary teeth sometimes referred to
561 *"Aublysodon*" (Carpenter 1982). Whereas some authors have interpreted the absence of denticles
562 as an ontogenetic character (Currie et al. 1990, Currie 2003a, Carr and Williamson 2004), the
563 denticles in TMP 1996.005.0011 indicate that this issue may be more complex than currently
564 recognized. Indeed, Currie (2003a) noted that premaxillary teeth of *Gorgosaurus* were always
565 serrated, whereas those of juvenile tyrannosaurines often lacked denticles on the carinae. This

566 hints that taxonomy may play a role in the ontogenetic development of denticles in
567 tyrannosaurids.
568
569 *MOR 268*—MOR 268 can be distinguished from other amniotes by a combination of
570 features present only in dinosaurs. Specifically, the thecodont mode of tooth implantation
571 distinguishes it from amphibians, terrestrial lepidosaurs, and fish (Owen 1845). The homodonty
572 of the dentition differentiates MOR 268 from the mandibles of mammals (Butler 1995). Within
573 Diapsida, the absence of an elongate symphysis and the depth of the alveoli distinguishes MOR
574 268 from the dentaries of neochoristoderes (Brown 1905). MOR 268 differs from the mandibles
575 of crocodylomorphs in lacking a medially-curved symphyseal region of the dentary, which is
576 present even in early embryos (Westergaard and Ferguson 1986, 1987). Within Dinosauria,
577 MOR 268 is most like theropods in the elongated and anteriorly tapering dentary, and the blade-
578 like teeth set in distinct sockets. Toothed theropods present in the Campanian of Laramidia
579 include alvarezsaurids (Longrich and Currie 2009, Fowler et al. 2020), dromaeosaurids (Currie
580 1995, Larson and Currie 2013, Evans et al. 2013, Currie and Evans 2019), enantiornithines
581 (Varricchio and Chiappe 1995, Atterholt et al. 2018), ornithuromorphs (Longrich 2009, Mohr et
582 al. 2020), troodontids (Currie 1987, Zanno et al. 2011), and tyrannosaurids (Russell 1970, Currie
583 2003a). We follow Funston et al. (2020) in interpreting caenagnathids as edentulous throughout
584 their lifetimes (contra Wang et al. 2018). However, even if they did possess teeth early in life,
585 the dentary of MOR 268 differs from those of caenagnathids in being much more elongate and
586 lacking a symphyseal shelf or upturned beak (Currie et al. 1993, Funston and Currie 2014). The
587 dentaries of alvarezsaurids and troodontids from the Late Cretaceous are distinct from MOR 268
588 in possessing numerous teeth that sit in an open groove rather than distinct alveoli (Currie 1987,

589 Chiappe et al. 2002). MOR 268 can be further distinguished from alvarezsaurids and troodontids
590 by the presence of interdental plates between adjacent alveoli. Furthermore, MOR 268 lacks the
591 medial curvature of the anterior portion of the dentary that is present in troodontids (Currie
592 1987). Like MOR 268, dromaeosaurid dentaries are straight with relatively few alveoli, but they
593 differ in that they lack a pronounced chin, an anterodorsally sloped anterior margin, an
594 anterodorsally angled anterior alveolar margin, and a large fossa at the anterior end of the
595 Meckelian groove (Currie 1995, Barsbold and Osmólska 1999, Currie and Evans 2019).
596 Interdental plates are fused in dromaeosaurids (Currie 1987, 1995), even in juvenile individuals
597 like *Bambiraptor feinbergi* (AMNH FARB 30556), and thus the unfused interdental plates of
598 MOR 268 are unlike those of dromaeosaurids. Chiarenza et al. (2020) recently described a small
599 dromaeosaurid dentary from the Prince Creek Formation of Alaska, and they provided several
600 characters to distinguish that specimen from tyrannosauroids. In each case, MOR 268 exhibits
601 the conditions Chiarenza et al. (2020) describe as distinguishing tyrannosauroids from
602 dromaeosaurids. This includes a deep Meckelian groove, contrasting with the shallow groove in
603 dromaeosaurids and other maniraptorans; an enlarged, rounded oral mandibular foramen, rather
604 than slit-like; and box-like alveoli, in contrast to the lenticular alveoli of dromaeosaurids
605 (Chiarenza et al. 2020). However, this latter character is more pronounced in the posterior alveoli
606 than the anterior alveoli of MOR 268, and thus is probably variable along the dentary in
607 tyrannosaurids—the same variation is described for *Nanuqsaurus* (Fiorillo and Tykoski 2014).
608 Two other characters mentioned by Chiarenza et al. (2020), specifically the presence of
609 dorsoventral furrows in the interdental plates and the well-developed interdenticular sulci of the
610 teeth, cannot be scored in MOR 268: the interdental plates are composed of porous bone without
611 a finished surface that could exhibit furrows, and the teeth do not yet have denticles.

612 Toothed birds also existed in the Late Cretaceous of western North America, but MOR
613 268 contrasts with each of these groups. The dentary of MOR 268 can be distinguished from
614 those of Enantiornithes and toothed ornithuromorphs by the presence of a distinct chin, a broad
615 anterodorsal projection of the alveolar margin, tightly spaced alveoli that are mesiodistally
616 elongate, numerous unorganized nutrient foramina on the anterolateral surface, and greater
617 relative dorsoventral depth of the dentary along the tooth row (O'Connor and Chiappe 2011,
618 Wang et al. 2020, Hu et al. 2020). The dentary of MOR 268 differs from both *Hesperornis* and
619 *Ichthyornis* in that it is anteriorly expanded, forming a distinct chin, rather than anteriorly tapered
620 (Dumont et al. 2016, Field et al. 2018). Furthermore, the Meckelian groove of MOR 268 is much
621 deeper than in either *Hesperornis* or *Ichthyornis*, and it terminates farther anterior (Dumont et al.
622 2016). At its termination, it merges with a deep fossa offset dorsally from a distinct, rounded oral
623 mandibular foramen, identical to the condition in tyrannosaurids (Carr and Williamson 2004,
624 Fiorillo and Tykoski 2014), but unlike those in *Hesperornis* or *Ichthyornis* (Dumont et al. 2016).
625 In contrast to its dissimilarity to other toothed theropods, MOR 268 exhibits several
626 tyrannosauroid synapomorphies. The Meckelian groove is dorsoventrally shallow and deeply
627 inset into the medial surface of the dentary; Loewen et al. (2013) recovered this as a
628 synapomorphy of a basal node of tyrannosauroids, including all tyrannosaurids. The position of
629 the transition between the anterior and ventral edges of the dentary below the fourth alveolus,
630 and the presence of a ventrally-projecting 'chin', were considered synapomorphies of
631 Tyrannosauridae + *Appalachiosaurus* + *Bistahieversor* by Brusatte et al. (2010). These character
632 states are both exhibited by MOR 268. The smaller size of the anterior two alveoli is a
633 synapomorphy of Tyrannosauroidea (Brusatte et al. 2010, Loewen et al. 2013, Carr et al. 2017).
634 MOR 268 cannot be confidently scored for this character because the first alveolus is not

635 preserved, but the second alveolus is smaller than the third. Considering that no theropod is
636 known where only the second alveolus is significantly smaller, we interpret the smaller second
637 alveolus of MOR 268 as indicative that the first two alveoli were smaller than the remaining
638 alveoli. Furthermore, some non-phylogenetic characters support the tyrannosaurid identity of
639 MOR 268. For example, the sinuous shape of the dorsal edge of the dentary in lateral view is
640 characteristic of tyrannosaurids (Carr and Williamson 2004). Specifically, the dorsal edge is
641 convex adjacent to the first four or five teeth, and convex posterior to this tooth position, like in
642 most tyrannosaurids (Carr and Williamson 2004). Furthermore, the deep Meckelian groove is at
643 about the mid-height of the dentary and it terminates anteriorly at an elliptical foramen at the
644 level of the fifth alveolus in all tyrannosaurids (Carr and Williamson 2004). In tyrannosaurids,
645 the interdental plates are well developed, unfused, and separated from the lingual wall of the
646 dentary by a step (Currie 2003a). Each of these conditions are exemplified by MOR 268,
647 consistent with other tyrannosaurids but contrasting with other theropods. Within
648 Tyrannosauridae, MOR 268 shows affinities with *Alioramus altai* and juvenile *Daspletosaurus*
649 *horneri* and *Gorgosaurus libratus* in several features (Fig. 8). The dentary is most similar in
650 proportions to that of *Alioramus altai* (Brusatte et al. 2009, 2012), in being elongate and low.
651 However, it contrasts with *Alioramus altai* in the better development of the ventrally-protruding
652 'chin' and the dorsal convexity of the anterior end of the alveolar margin (Brusatte et al. 2012).
653 MOR 268 is similar to the dentaries of small juvenile *Daspletosaurus horneri* and *Gorgosaurus*
654 *libratus* in shape, proportions, and the presence of an intermediate row of foramina on the lateral
655 surface of the dentary (Fig. 8). In each, anterior surface of the dentary is strongly inclined, and its
656 transition point with the ventral surface of the dentary is gradual and rounded. In slightly larger
657 juveniles and adults, the anterior surface of the dentary is more upturned and the transition with

the ventral surface is more abrupt. MOR 268, TMP 1994.012.0155 and MOR 553S 7-19-0-97 each have a prominent middle row of foramina on the lateral surface of the dentary that merges posteriorly with the ventral row. The confluence of these rows is situated further anterior in each of the successively larger specimens. Despite its general similarity to juvenile tyrannosaurids, MOR 268 differs in some finer details from *Daspletosaurus horneri* (MOR 553S 7-19-0-97), which is the only tyrannosaurid known from the Two Medicine Formation (Carr et al. 2017). In particular, it lacks the distinctive laterally bowed dentary that Carr et al. (2017) suggested was diagnostic of *Daspletosaurus horneri*, although this may be developed later through ontogeny. Also, the anterior alveoli do not project anteromedially in MOR 268, although this region is poorly preserved and this character may also have been developed later in ontogeny as the dentary became laterally bowed. In *Daspletosaurus* spp., the transition point between the anterior and ventral edges of the dentary is situated below the third alveolus, which Carr et al. (2017) interpreted as a synapomorphy of the genus. In MOR 268, this transition point is below the fourth alveolus, which is more similar to other tyrannosaurids. Thus, MOR 268 cannot be referred with certainty to *Daspletosaurus horneri*, although based on its provenance, this is the most likely candidate for its identity.

Size of hatchling tyrannosaurids:

Considering that the developmental stages of the specimens can be roughly constrained, some preliminary insights into the general size of hatchling tyrannosaurids can be made. Regression analyses of measurements obtainable from MOR 268 (dentary minimum height) and UALVP 59599 (ungual II-3 length) each showed significant regressions with high predictive

value (r^2= 0.788-0.959, p-value < 0.001; Tables 2, 3; Figs. 9, 10) to other measurements useful for estimating body size. In the case of MOR 268, the minimum height of the dentary produced reasonable estimates of dentary length (55 mm; 95% CI: 39–72 mm), considering the preserved length of the dentary (29 mm; Table 1). However, reconstruction of the dentary of MOR 268 by comparison to the dentaries of other juvenile tyrannosaurids (Figs. 5, 8) suggests that estimates closer to the lower bound of 39 mm are more probable. A relatively shorter dentary at this early stage of development might be expected, as shorter snouts have been reported for embryos and perinates in various other dinosaur groups (Horner and Currie 1994, Kundrát et al. 2007, Fastovsky et al. 2011, Chapelle et al. 2020). Estimated skull and jaw length for MOR 268 are 90 mm (CI: 69–111 mm) and 86 mm (CI: 67–104 mm), respectively, which fit well with the dentary length estimate based on previous tyrannosauroid skull regressions (Currie 2003b). Furthermore, these independently-derived estimates are close in length, as would be expected of the mandible and skull of a single individual. The skull length estimate compares well to the hypothetical hatchlings proposed by Russell (88 mm; 1970) and Currie (95 mm; 2003b). However, the femoral length for these studies was arbitrarily set at 100 mm and the regressions here suggest that the femur of MOR 268 was smaller (85 mm; CI: 71–103 mm). Critically, the developmental stage of MOR 268 suggests it was some time from hatching, and this may account for this discrepancy. Nonetheless, the upper bound of the confidence interval (103 mm) is just slightly larger than the arbitrary 100 mm proposed by Currie (2003b) and Russell (1970), so their estimates are still within the realm of the new data. Both Currie (2003b) and Russell (1970) estimated a skull shorter than the femur in a hatchling tyrannosaurid. Our estimates (Table 3) contradict this, but allometric trends are unknown for embryos and hatchlings of any theropod, especially tyrannosaurids, and a linear regression analysis may not account for the many changes

704 the cranium undergoes during early development. It has been previously suggested that there is a
705 period of snout elongation in dinosaurs after hatching (Kundrát et al. 2007, Chapelle et al. 2020)
706 and the skull has been shown to deepen dorsoventrally through ontogeny in tyrannosaurids (Carr
707 1999, 2020, Currie 2003b). Therefore, linear regressions may not capture the initial elongation
708 expected in theropod hatchlings, and so the lower estimates for skull dimensions are probably
709 more favourable.
710 Size estimates for UALVP 59599 using pedal ungual II-3 length (Tables 2, 3) resulted in
711 lower values for hindlimb elements than predicted by Currie (2003b) but greater than those of
712 Russell (1970) (except for digit III length). However, the estimated femur length was greater
713 than their 100 mm baseline (Table 3). The regression estimated a femur length of 136 mm (CI:
714 76–256 mm) for UALVP 59599. The lower bound of the confidence interval (76 mm) is roughly
715 the same size as the femur of the perinatal holotype of the giant oviraptorosaur *Beibeilong*
716 *sinensis* (75 mm; Pu et al. 2017), whereas the lower limit for MOR 268 (71 mm) is slightly
717 smaller. The upper bound of the femoral length estimate for UALVP 59599 (256 mm) is greater
718 than the femoral length of the early tyrannosauroid *Dilong paradoxus* (185 mm; Xu et al. 2004)
719 and just shorter than the femoral length of the smallest *Tarbosaurus bataar* specimens
720 ("*Shanshanosaurus*" IVPP 4878, 285 mm; MPC-D 107/7, 303 mm). Considering the latter
721 specimen is approximately three years old (Tsuihiji et al. 2011), this is clearly an overestimate
722 for an embryonic individual.
723 Estimations of total body length (Fig. 11) for MOR 268 (715 mm) and UALVP 59599
724 (1101 mm) are reasonable estimates given those for femur length (MOR 268 – 86 mm; UALVP
725 59599 – 136 mm). The estimate of total length for MOR 268 is similar to, but smaller than the
726 sum of the skull and vertebral column estimated by Russell (768 mm; 1970) (Table 3). A smaller

727 body length estimate for MOR 268 compared to Russell's (1970) hypothetical hatchling is
728 logical, as the femoral length estimate (85 mm) was also lower and this individual was in the
729 middle stages of embryonic development, rather than close to hatching. The greater total body
730 length estimate for UALVP 59599 (1101 mm) is also reasonable given its greater femoral length
731 estimate (136 mm). The confidence interval for total body length in UALVP 59599 (CI: 250–
732 5954 mm) is much wider than that recovered for MOR 268 (CI: 496–897 mm; Table 2). This
733 suggests that in tyrannosauroids the minimum height of the dentary is more tightly linked to total
734 body length than the length of pedal ungual II-3.
735 The estimates produced by regression seem reasonable given the overlap with previous
736 hypotheses of hatchling tyrannosaurid dimensions (Russell 1970, Currie 2003b) and the
737 existence of other theropod perinates of similar size (Pu et al. 2017). The close proximity in size
738 of UALVP 59599 to the embryonic unguals of the recently extinct Elephant Bird *Aepyornis*
739 (Balanoff and Rowe 2007) further support that embryos and hatchlings of such large size are
740 reasonable. Although the estimates of total body length may seem large for embryos, the largest
741 theropod eggs known are approximately 450 mm along their long axis (Pu et al. 2017, Simon et
742 al. 2019) and the curled bodies of tyrannosaurid embryos could easily fit into an egg of similar
743 size at their estimated lengths. Given the developmental stages interpreted for these embryonic
744 specimens, they can be expected to have grown even larger before hatching. Therefore,
745 tyrannosaurids may have had eggs of even larger size than those of *Beibeilong sinensis* to
746 accommodate these large embryos. Altogether, considering that UALVP 59599 is approximately
747 10–15% larger in size than the *Aepyornis* unguals described by Balanoff and Rowe (2007), and
748 the femoral length estimates of both MOR 268 and UALVP 59599 are larger than the femur of

perinatal *Beibeilong sinensis*, tyrannosaurids may have produced some of the largest terrestrial egg-enclosed embryos.

Nesting habits of tyrannosaurids:

The sedimentology and taphonomic profiles of the sites that produced the embryonic material provide clues to the nesting habits of tyrannosaurids, and why their eggs and embryos remain elusive.

The FTS-2 site is unusual compared to other HCF microsites in several respects. Microfossils at this locality are not concentrated in a single lens, but rather accumulated by weathering from an unusual, massive mudstone with paleosol development. This lithology is uncommon in the Horsethief Member of the HCF, although two other such sites are known: another less productive site in the Morrin Bridge Area, and L2000 in Horsethief Canyon (Ryan et al. 1998). Of these, FTS-2 has the most diverse assemblage, also producing embryonic remains of troodontids, anuran bones, mammalian teeth, silicified plant seeds, and eggshell, all of which is referable to *Prismatoolithus levis* (Zelenitsky and Hills 1996, Funston and Currie 2018a). A full description of the assemblage is currently underway (Whitebone, Funston, and Currie in prep.), but several peculiarities are worth noting here. Beyond the presence of rare taxa and ontogenetic stages, FTS-2 is also unusual in the absence or rarity of fossils that are usually common throughout the HCF: *Champsosaurus*, crocodylians and turtles are completely absent, as are *Myledaphus* teeth, and fish scales are uncommon. These absences probably reflect environmental differences rather than taphonomic biases, as larger skeletal bones, like hadrosaurid ribs and vertebrae, are known from all these sites. The abundance of anurans indicates an absence of marine influence, and the absence of aquatic reptiles indicates relatively

772 little fluvial influence on the site, which was therefore probably far inland. Similarly, the Egg
773 Gulch locality in the Two Medicine Formation comprises interbedded mudstones and caliches
774 that are indicative of an arid, inland environment. This site produces abundant eggs and nests of
775 *Maiasaura*, indicating that it was a frequent nesting site. Both localities produce assemblages
776 that include eggshell and embryonic bones of other dinosaurs, especially hadrosaurids and
777 troodontids. This suggests that tyrannosaurids nested in the same environments as these animals,
778 specifically sites with minimal marine or fluvial influence. Accordingly, there is presently no
779 evidence that the rarity of tyrannosaurid embryos or eggs is the result of different nesting habits
780 compared to other dinosaurs. Thus, it is perplexing that no potential tyrannosaurid eggshell has
781 been found, as it would be expected to be relatively thick and easily preserved compared to other
782 dinosaur eggshell, based on estimates of hatchling size above. Indeed, fragments of *Maiasaura*
783 eggshell (Hirsch and Quinn 1990) are preserved in the same block as MOR 268, and the FTS-2
784 site produces the only eggshell known from the HCF (Funston and Currie 2018a), which
785 suggests that tyrannosaurid eggshell could have been preserved at each site if it were present.
786 While it could be argued that the continued rarity of tyrannosaurid eggs is simply because
787 tyrannosaurids were less common members of their respective faunas, this does not appear to be
788 the case (Horner et al. 2011, Currie 2016, Funston et al. 2018). A possible explanation may lie in
789 the recent discovery that dinosaurs ancestrally laid soft-shelled eggs (Norell et al. 2020). If
790 tyrannosaurids laid plesiomorphic soft-shelled eggs, this would explain the discrepancy in their
791 rarity. However, current evidence casts doubt on this possibility: in the analysis of Norell et al.
792 (2020), tyrannosaurids are nested between theropod groups that had calcified eggs. It is possible
793 that tyrannosaurids secondarily reversed to a soft-shelled egg, or that the calcified eggs of
794 megalosauroids and maniraptorans originated independently, but there is currently no evidence

795 to support either of these claims. In any case, the absence of tyrannosaurid eggshell associated
796 with the embryonic bones—even though these are found together for other dinosaurs in the same
797 sites—is unusual and worthy of further investigation. The distinctiveness of the lithologies and
798 assemblages of FTS-2 and Egg Gulch is promising for the identification of similar sites for
799 targeted prospecting. Continued surface collection and bulk sampling in each of the known sites
800 may produce more perinatal tyrannosaurid material—and perhaps the first identifiable
801 tyrannosaurid eggs or eggshells.
802
803 **Conclusions**
804 The embryonic bones and perinatal teeth of tyrannosaurid dinosaurs described here provide a
805 window into the earliest development of these colossal predators. Some of the characters
806 distinguishing tyrannosaurids from other theropods later in life are already present during the
807 earliest stages of development. The dentary of the embryonic tyrannosaurid MOR 268 is
808 remarkably similar to those of juvenile tyrannosaurids, and contrasts strongly with the dentaries
809 of other theropods. Similarly, a premaxillary tooth exhibits the distinctive D-shaped cross-
810 section and longitudinal ridge present in all adult tyrannosaurids, as well as incipient serrations.
811 Based on the embryonic dentary and ungual, tyrannosaurid hatchlings would have been
812 relatively large compared to other dinosaurs, and previous estimates of hatchling size were
813 surprisingly accurate considering the lack of known perinatal material at the time. The rarity of
814 tyrannosaurid embryonic material and the absence of eggshell at nesting sites is perplexing and
815 requires further investigation, but current evidence suggests that tyrannosaurid perinates should
816 be present in nesting assemblages of other dinosaurs.

1347 Table 1. Selected measurements of perinatal tyrannosaur specimens.

Taxon	Specimen	Element	Measurement	Value (mm)
cf. *Albertosaurus sarcophagus*	UALVP 59599	Ungual ?IV-5	Length	10
			Proximal height	6.2
			Proximal width	5.3
	TMP 1996.015.0011	Premaxillary tooth	Total length	16.4
			Crown length	8.5
			Fore-aft basal length	3.5
			Basal width	2.6
cf. *Daspletosaurus horneri*	MOR 268	Dentary	Length	29.2 (preserved)
			Minimum height	3.29
			Height at 'chin'	4.1
			Transverse width at symphysis	1.5
			Length of alveolus 2	0.7
			Length of alveolus 3	1.14
			Length of alveolus 4	1.17
			Length of alveolus 5	1.56
			Length of alveolus 6	1.49
			Length of alveolus 7	1.56
			Length of alveolus 8	1.67
			Length of alveolus 9	1.38
			Length of alveolus 10	1.52 (estimated)
			Tooth row	26 (estimated)
		Tooth 2	Height	0.52
			Fore-aft basal length	0.37
			Basal width	0.22
		Tooth 4n (t1 generation)	Height	2.35 (preserved)
			Fore-aft basal length	0.85
			Basal width	0.34
		Tooth 4	Height	0.83
			Fore-aft basal length	0.59
			Basal width	0.22
		Tooth 5	Height	2.62
			Fore-aft basal length	1.24
			Basal width	0.31
		Tooth 6	Height	1.41
			Fore-aft basal length	0.815
			Basal width	0.36
		Tooth 7	Height	0.35
			Fore-aft basal length	0.24
			Basal width	0.212
		Tooth 8	Height	1.80
			Fore-aft basal length	1.24
			Basal width	0.23

Tooth 10	Height	1.99
	Fore-aft basal length	0.95
	Basal width	0.22

1348

1349

1350

1351 Table 2. Results of reduced major axis regressions of selected measurements for tyrannosauroids,

1352 with size estimates for perinatal specimens described here.

Specimen	Independent variable (x)	Dependent variable (y)	n	Slope interval (m)	Intercept interval (b)	Estimated value (mm)	95% Confidence Interval (mm)
MOR 268	Dentary, min height (Dent Min H)	Dentary length (Dent L)	59	0.658, 0.761	1.261, 1.478	**54.7**	**39.2 – 72.7**
	Dent Min H	Jaw Length (L)	45	0.663, 0.737	1.490, 1.645	**86.4**	**66.8 –104.0**
	Dent Min H	Skull Length	63	0.628, 0.710	1.522, 1.687	**89.6**	**69.04 – 111.0**
	Dent Min H	Femur Length	92	0.658, 0.720	1.520, 1.647	**85.2**	**71.2 – 102.6**
	Dent Min H	Total Body Length (L)	27	0.661, 0.759	2.362, 2.569	**715.2**	**496.4 – 896.6**
UALVP 59599	Phalanx II-3 length (II-3 L)	Digit III Length	24	0.745, 1.036	0.484, 1.071	**50.5**	**16.9 – 127.9**
	II-3 L	MT III Length	27	0.428, 0.590	1.515, 1.847	**156.4**	**87.7 – 273.7**
	II-3 L	Tibia Length	28	0.482, 0.634	1.609, 1.923	**211.5**	**123.4 – 360.9**
	II-3 L	Femur Length	42	0.662, 0.835	1.218, 1.574	**135.87**	**76.0 – 256.4**
	II-3 L	Total Body Length	16	0.522, 0.972	1.876, 2.803	**1100.6**	**250.0 – 5954.6**

Note: Estimations of the dependent variable (y) were produced using the power function of the RMA regression equations using the independent variable (x) of the relevant specimen.

1356 Table 3. Comparisons of tyrannosaurid embryo dimensions to previous hypothetical hatchlings.

Element	MOR 268	UALVP 59599	Currie (2003)	Russell (1970)
Skull	89	–	95	88
Presacral vertebrae	–	–	–	210
Sacrum	–	–	–	70
Tail (first 24 vertebrae)	–	–	–	390
Total Length (sum of first four rows for Russell 1970)	715	1101	–	768
Dentary length	55	–	–	–
Jaw Length	86	–	–	–
Femur Length	85	136	100	100
Tibia Length	–	212	224	140
MT III length	–	156	273	85
Digit III length	–	51	59	56

1357 **Note**: Estimated dimensions are based on power functions for the RMA regression equations in
1358 Figs. 9 and 10 and plotted along the regressions. All measurements are in millimeters. '–'
1359 indicates dimensions not estimated.

Figure Captions:

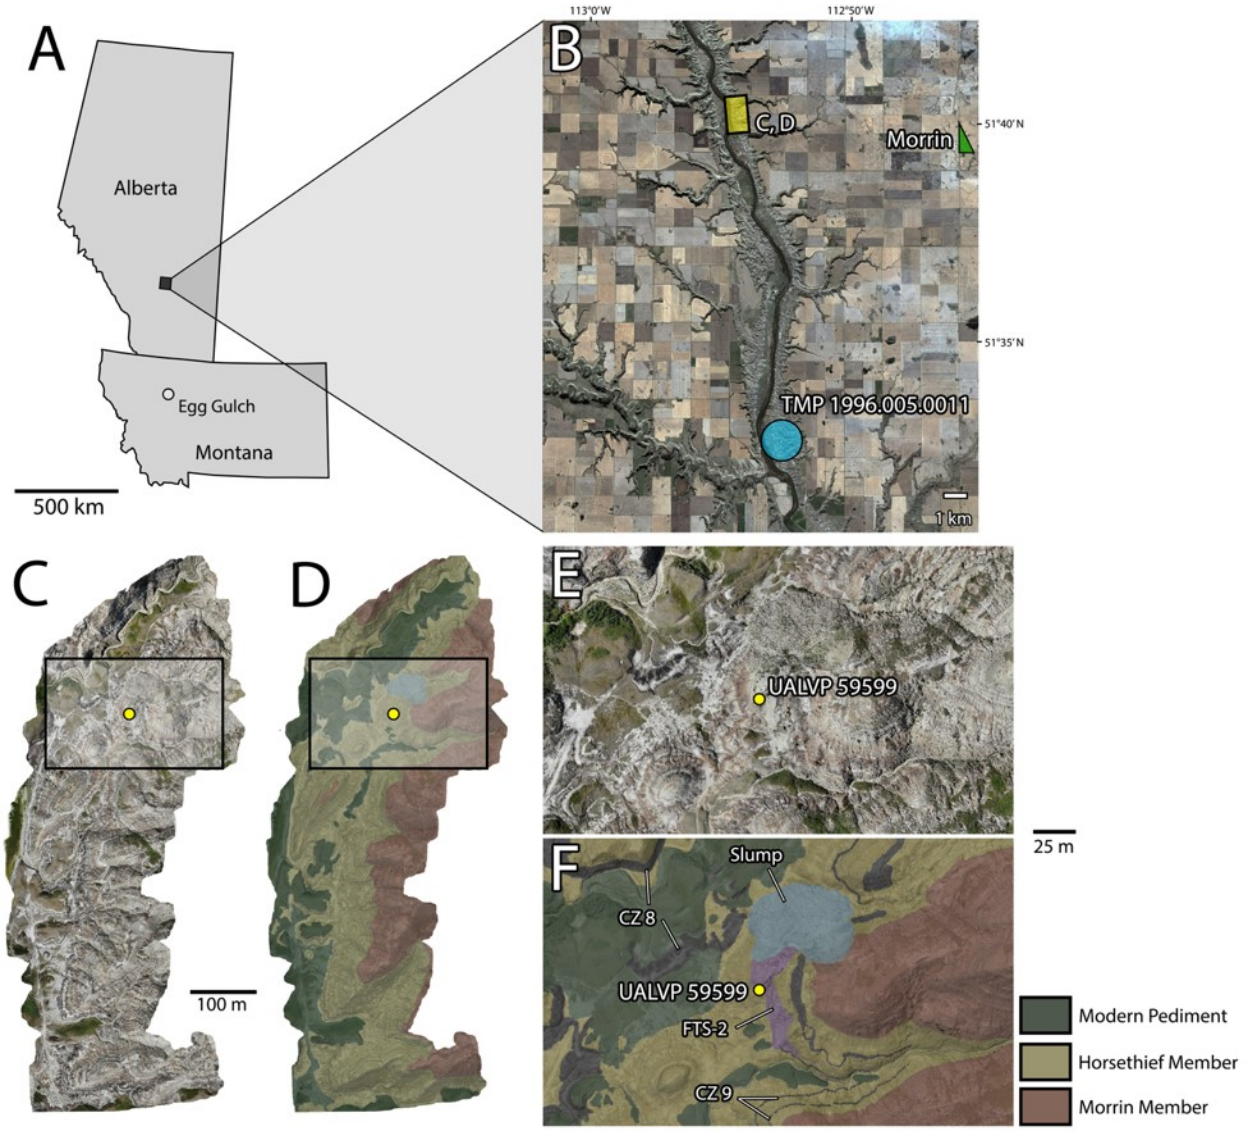

Fig. 1. Localities producing perinatal tyrannosaur bones. Map (A) of Alberta and Montana, showing the Egg Gulch locality and the location of the Red Deer River Valley region near Morrin, Alberta in (B). Satellite image (B) of Red Deer River Valley near Morrin, Alberta, showing locality of TMP 1996.005.0011 and the area mapped by an unmanned aerial vehicle shown in (C, D). Photogrammetric model (C, D) of eastern Morrin Bridge area created from 1080 photographs in natural colour (C) and false colour (D), showing the Horsethief (yellow)

and Morrin (red) Members, as well as modern pediment (green). Boxes indicate regions expanded in (E, F), and the yellow dot indicates the FTS-2 locality. Close-up of photogrammetric model (E, F), showing the FTS-2 locality and the area where UALVP 59599 was collected in natural colour (E) and false colour (F). Map data in (A, B) from Google, used under fair use terms. Abbreviations: **CZ**, coal zone.

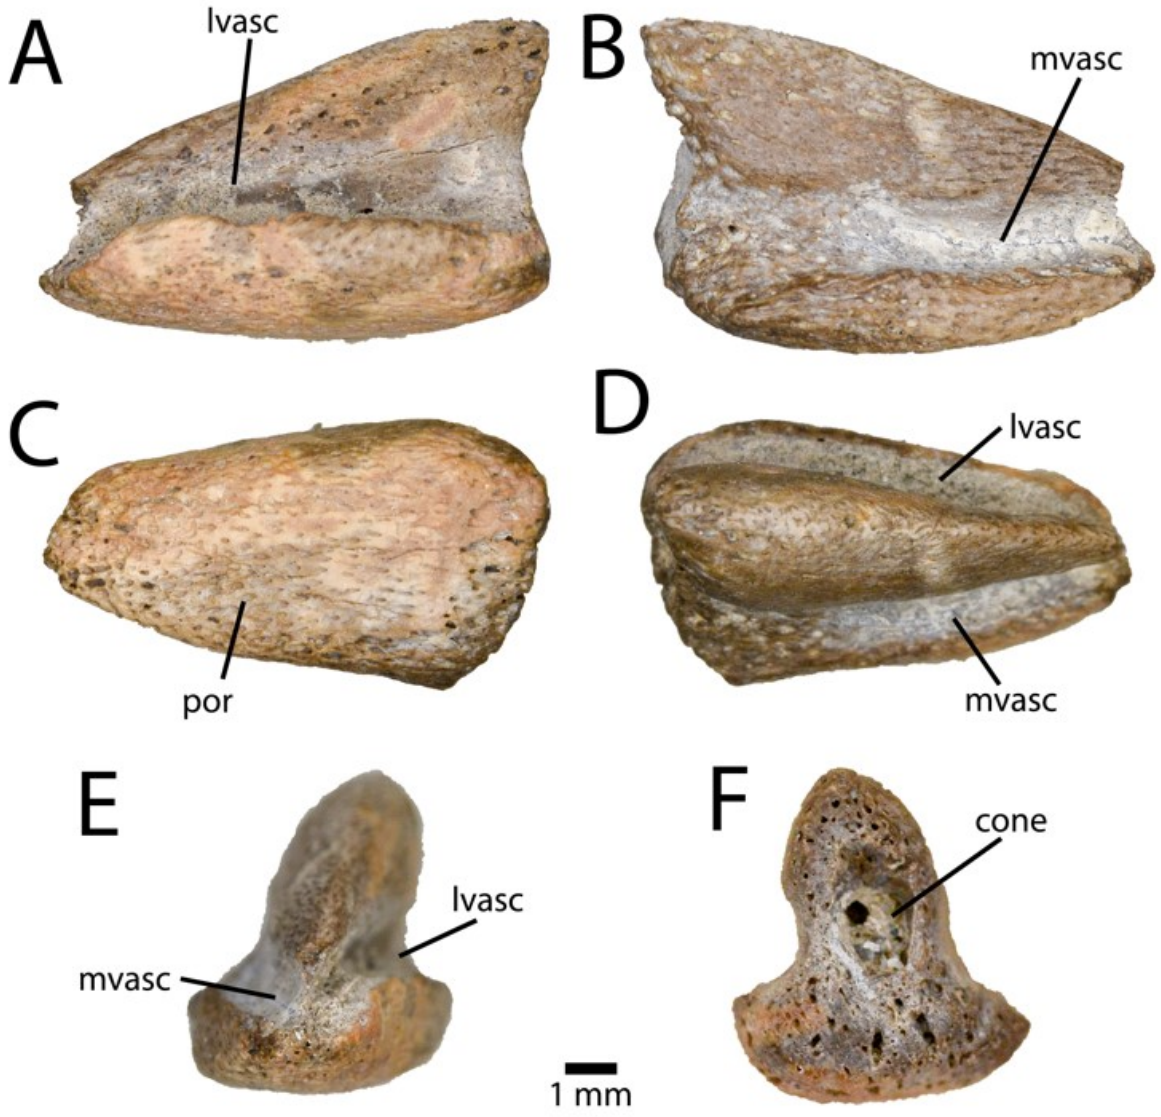

Fig. 2. Embryonic pedal ungual (left II-3) of cf. *Albertosaurus sarcophagus*. UALVP 59599 in lateral (A), medial (B), ventral/plantar (C), dorsal (D), distal (E), and proximal (F) views. **Abbreviations: cone**, space for cartilage cone; **lvasc**, lateral vascular canal; **mvasc**, medial vascular canal; **por**, porous bone texture.

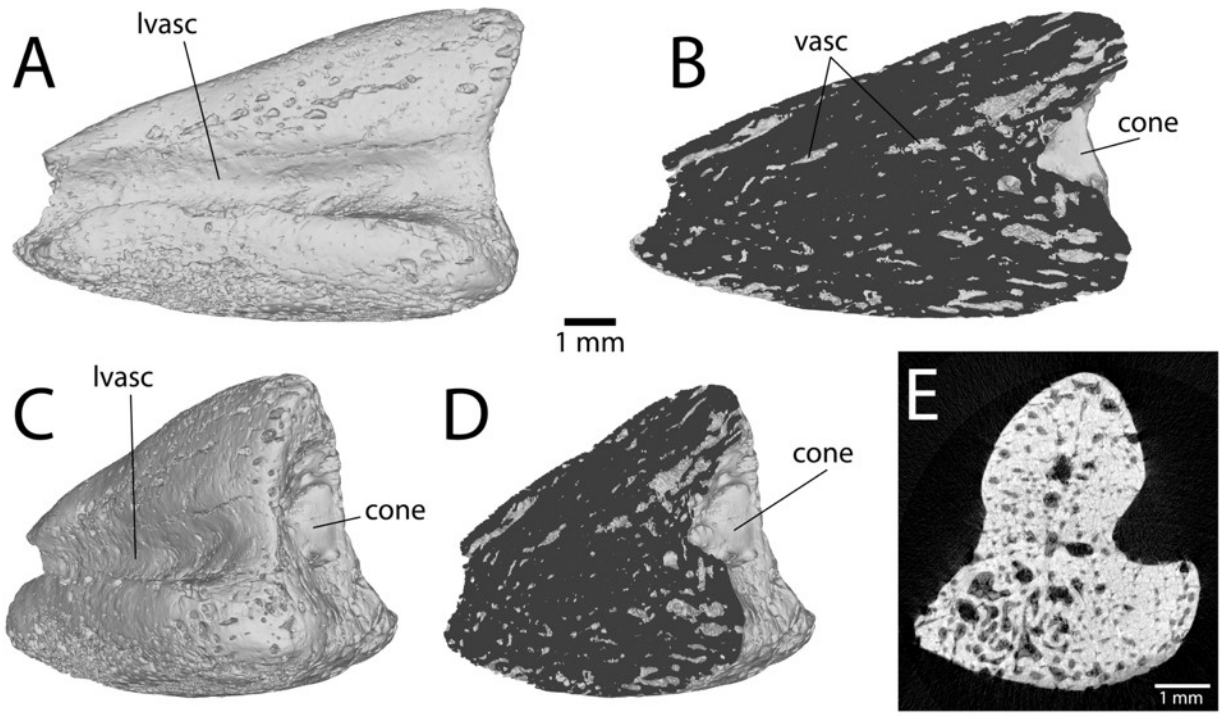

1381

1382 **Fig. 3.** µCT reconstruction of UALVP 59599 showing the porous bone texture and depth of the
1383 space for the cartilage cone. Surface model in lateral view (A), and the same view with the
1384 model clipped at a plane approximating the midline (B). Surface model in proximolateral view
1385 (C) and the same view with the model clipped at a plane approximating the midline (D). Dark
1386 areas in (B, D) represent back-faces of the mesh, not solid regions of bone. µCT slice (E) of
1387 UALVP 59599, showing porous internal structure. Lighter regions in (E) indicate areas of higher
1388 density.

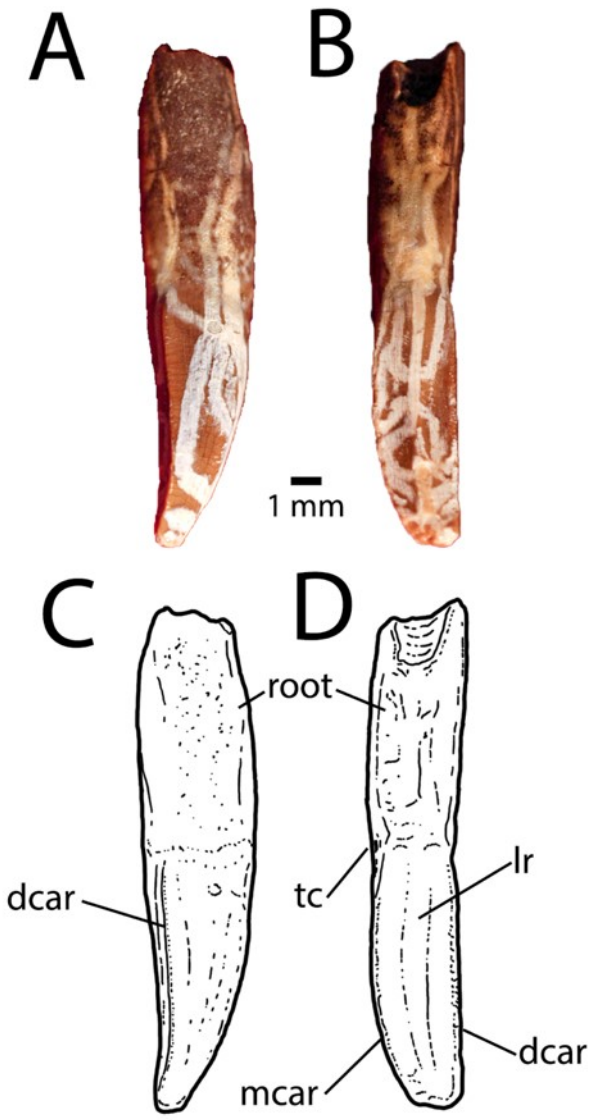

Fig. 4. Premaxillary tooth of a perinatal tyrannosaurid. TMP 1995.005.0011 (A–D; cf. *Albertosaurus sarcophagus*) in distal (A) and lingual (B) views, and interpretive illustrations in distal (C) and lingual (D) views. **Abbreviations: dcar**, distal carina; **lr**, longitudinal ridge; **mcar**, mesial carina; **root**, tooth root; **tc**, transverse constriction.

1405

1406

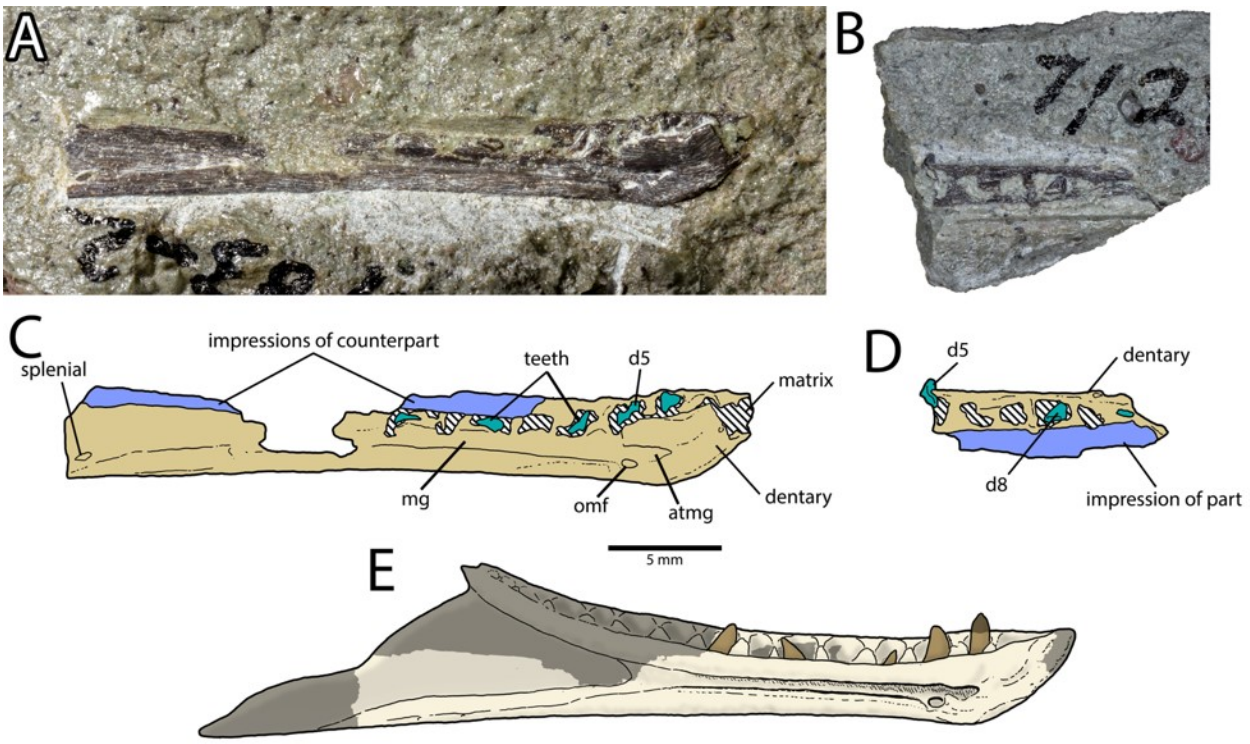

Fig. 5. Embryonic left dentary of cf. *Daspletosaurus horneri*. MOR 268 part in medial view (A), counterpart in lateral view (B), and interpretive illustrations of the same views (C, D, respectively). Hypothesized reconstruction of MOR 268 in life (E) based on comparison to other juvenile tyrannosaurid dentaries. Shaded areas are not preserved in MOR 268. All images are at the same scale. **Abbreviations: atmg**, anterior termination of Meckelian groove; **d5**, tooth 5; **d8**, tooth 8; **mg**, Meckelian groove; **omf**, oral mandibular foramen.

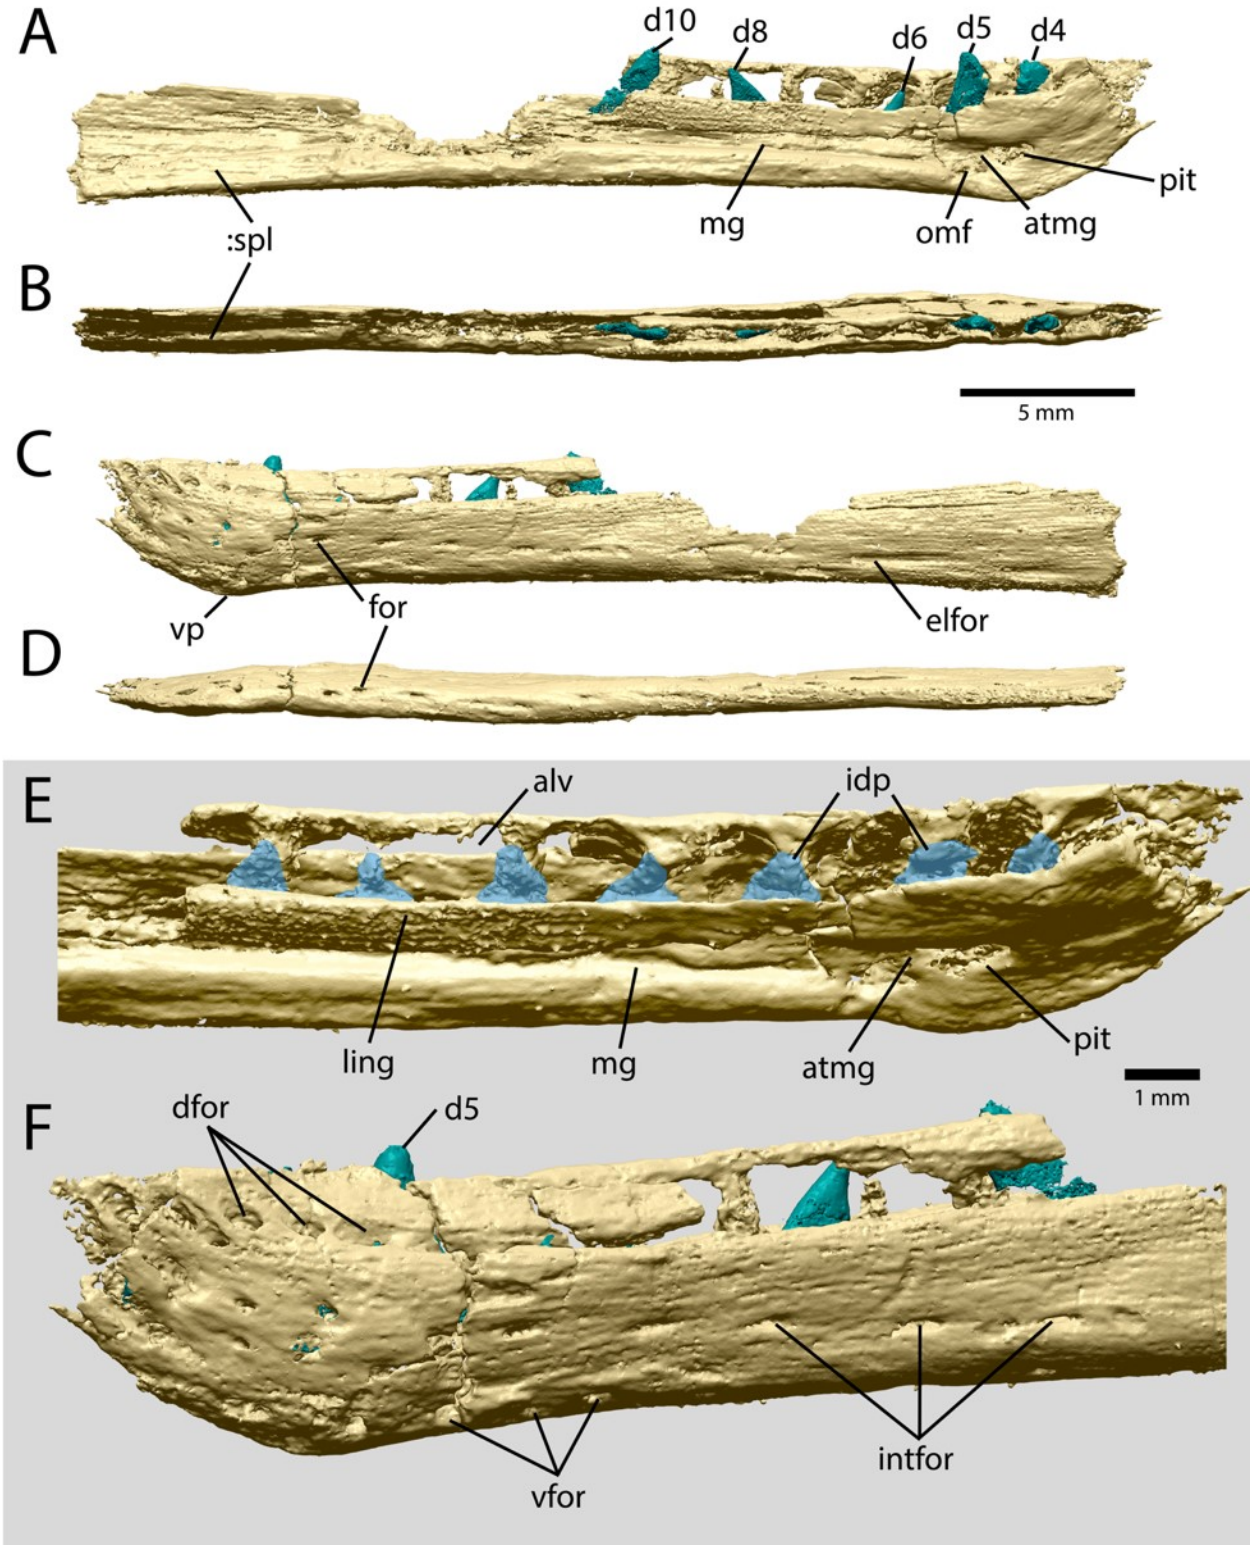
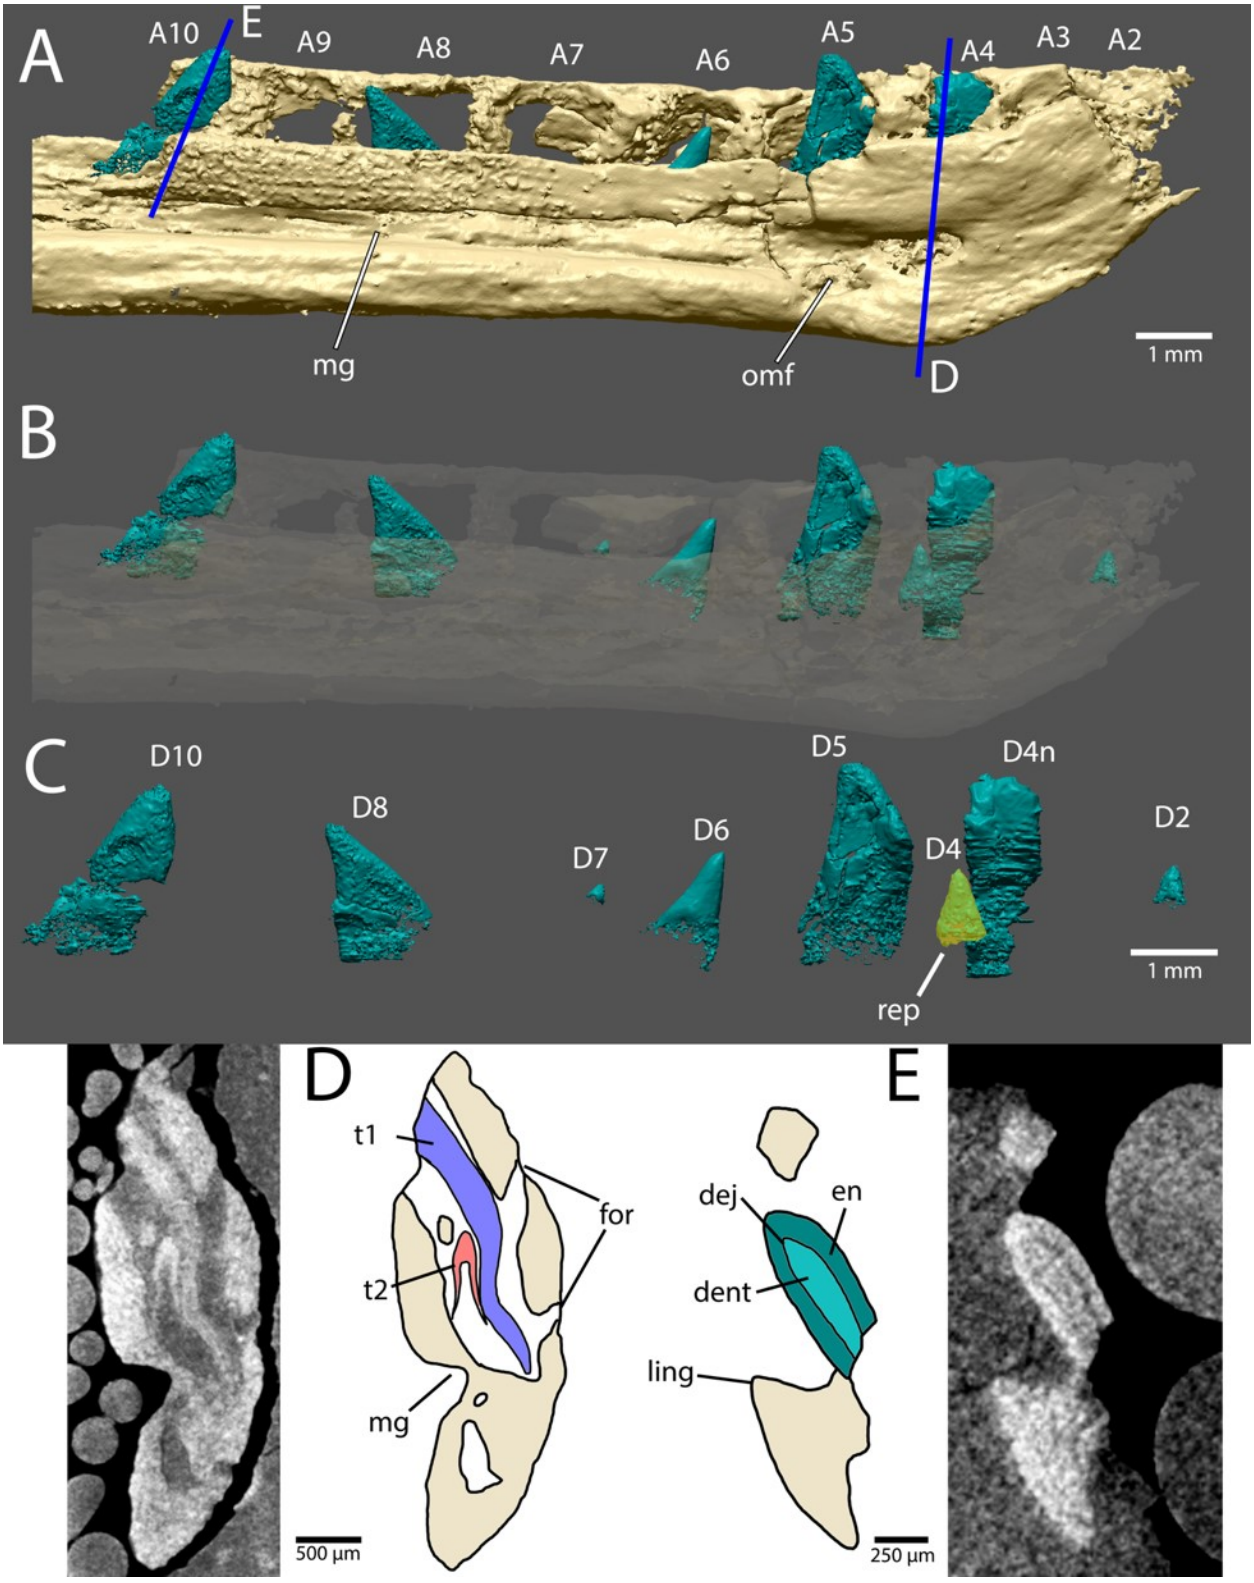
1417



1418 **Fig. 6.** Synchrotron μCT reconstruction of MOR 268 with part and counterpart reunited. Surface

model in medial (A), dorsal (B), lateral (C), and ventral (D) views. Close-up (E) of anterior part of the dentary in dorsomedial view with the teeth removed, showing the alveolar spaces and the interdental plates (highlighted in light blue). Close-up (F) of anterior part of the dentary in anterolateral view, showing rows of foramina. Teeth are represented in teal, bone is represented in beige. **Abbreviations: atmg**, anterior termination of Meckelian groove; **alv**, alveoli; **dfor**, dorsal row of foramina; **d4–10**, teeth 4 to 10; **elfor**, elongate foramen; **for**, foramen; **idp**, interdental plates; **intfor**, intermediate row of foramina; **ling**, lingual wall of dentary; **mg**, Meckelian groove; **omf**, oral mandibular foramen; **pit**, pit at the anterior end of the Meckelian groove; **vfor**, ventral row of foramina; **vp**, ventral protrusion; **:spl**, contact surface for splenial.

1429



1430 **Fig. 7.** Synchrotron µCT reconstruction of the teeth of MOR 268. Surface model of the anterior

part of the dentary in medial view (A), showing the locations of the visible teeth and the planes of section in images (D) and (E). Surface model of the anterior part of the dentary in medial view (B) with the bone rendered transparent, showing the morphology and positions of all the teeth. Surface model of the teeth in medial view (C) with the dentary removed, showing the relative development of the teeth and the presence of a replacement tooth in the fourth tooth position. Synchrotron μCT slice and interpretive illustration (D) showing the arrangement of the two teeth in alveolus four, and the absence of resorption or intervening mineralized tissue. Synchrotron μCT slice and interpretive illustration (E) of tooth 10 as preserved in the counterpart, showing the dentino-enamel junction. **Abbreviations: A2–A10**, alveoli two to ten; **D2–10**, teeth two to ten; **D4n**, t1 (null) generation tooth in the fourth position; **dej**, dentino-enamel junction; **dent**, dentine; **en**, enamel; **for**, foramen; **ling**, lingual wall of the dentary; **mg**, Meckelian groove; **omf**, oral mandibular foramen; **rep**, replacement tooth; **t1**, t1 (null) generation tooth; **t2**, t2 (functional) generation tooth.

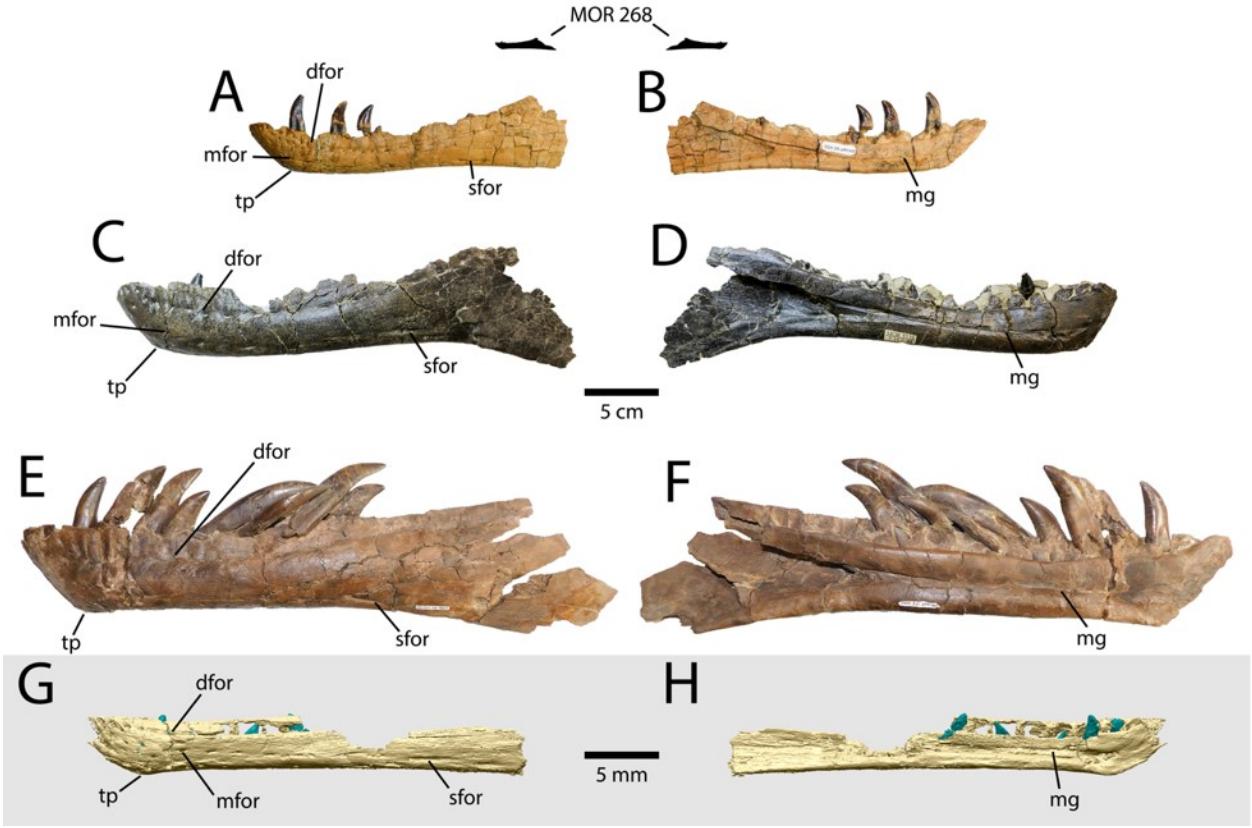


Fig. 8. Comparison of juvenile tyrannosaurid dentaries from the Late Cretaceous of Western North America. TMP 1994.012.0155 (mirrored; *Gorgosaurus libratus*) in lateral (A) and medial (B) views; MOR 553S 7-19-0-97 (*Daspletosaurus horneri*) in lateral (C) and medial (D) views; and TMP 1994.143.0001 (mirrored; *Gorgosaurus libratus*) in lateral (E) and medial (F) views, to the same scale. Note silhouette of hypothetical reconstruction of MOR 268, showing small size relative to other specimens. Synchrotron μCT reconstruction (G, H) of MOR 268 in lateral (G) and medial (H) views, enlarged 10× for morphological comparison to other specimens. **Abbreviations: dfor**, dorsal row of foramina; **mfor**, intermediate row of foramina; **mg**, Meckelian groove; **sfor**, slit-like foramen; **tp**, transition point between anterior and ventral edges of dentary.

Fig. 9. Reduced major axis regressions of tyrannosauroid minimum dentary height compared to various skull- and body size-related variables. Dependent variables dentary length (A), jaw length (B), skull length as measured from premaxilla to occipital condyle (C), femur length (D), and total length (E), were compared to minimum dentary height across tyrannosauroid specimens to estimate these measurements for the individual represented by MOR 268. MOR 268 was plotted onto the regression as a blue inverted triangle after the analysis, based on the dependant variable values estimated by the regression. Data points are coloured by taxonomic groupings: tyrannosaurines (blue squares), albertosaurines (orange circles), and non-tyrannosaurid tyrannosauroids (open grey squares).

Fig. 10. Reduced major axis regressions of tyrannosauroid pedal ungual II-3 to various hindlimb and body-size-related variables. Dependent variables digit III length (A), metatarsal III length (B), tibia length (C), femur length (D), and total body length (E), were compared to pedal ungual II-3 length across tyrannosauroid specimens to estimate these measurements for the individual represented by UALVP 59599. UALVP 59599 was plotted onto the regression as an orange inverted triangle after the analysis based on the dependant variable values estimated by the regression. Data points are coloured by taxonomic groupings: tyrannosaurines (blue squares), albertosaurines (orange circles), and non-tyrannosaurid tyrannosauroids (open grey squares).
