Highlights

Hydro-morphodynamics 2D modelling using a discontinuous Galerkin discretisation

- Implementation of a new morphodynamic model within a code generating framework
- Novel use of discontinuous Galerkin based finite element methods to solve this system
- Model simulates suspended and bedload transport with gravity and helical flow effects
- Successful validation evidence through standard trench migration and meander cases
Hydro-morphodynamics 2D modelling using a discontinuous Galerkin discretisation

1. Introduction

Data from 2010 shows that almost 400 million people lived in areas less than 5m above average sea level (CIESIN, 2013) and this population keeps growing. As sea levels rise and with the potential for storms to increase in strength and frequency due to a changing climate, the coastal zone is becoming an ever more critical location for the application of advanced modelling techniques. A significant example is the development and application of improved morphodynamic models to simulate sediment transport accurately. The effects of climate change will cause hydrodynamic changes leading to increased erosion risk in coastal zones. The coupled and non-linear nature of this problem makes it especially challenging, since models must solve both hydrodynamic and sediment transport processes together with their two-way coupled interactions. Furthermore, there are two types of sediment transport processes that should be resolved: suspended sediment in the fluid and bedload transport propagating along the bed itself.

Over the last 40 years, increasingly sophisticated morphodynamic models have been developed to predict sediment transport in fluvial and coastal zones. These models can be one-dimensional (1D), two-dimensional (2D) or three-dimensional (3D), and are discussed in detail in Amoudry (2008), Amoudry and Souza (2011) and Papanicolaou et al. (2008), which we draw upon for a brief review here. 1D models generally use finite difference methods to solve a simple system of equations and are the cheapest computationally. However, they cannot capture velocity in the cross-stream and vertical directions. 2D (or 2DH) models adopt the shallow water approximation and can use finite difference (e.g. XBeach – Roelvink et al., 2015), finite volume (e.g. Mike 21 – Warren and Bach, 1992), or finite element based methods to solve a more complex system of equations. They capture velocity in both the streamwise and cross-stream directions on planview geometries in the horizontal. 3D models are similar to 2D, but solve an even more complex full system of equations using finite difference (e.g. ROMS – Warner et al., 2008), finite volume (e.g. Fast3d – Landsberg et al., 1998) or finite element based methods. They are thus potentially more accurate, but considerably more computationally expensive. Established modelling frameworks offer 2D and 3D options, such as Telemac-Mascaret (Hervouet, 1999) and Delft3d (Deltares, 2014), which use finite element/volume and finite difference based methods, respectively. In choosing a model, one must balance the simplicity and computational efficiency of a 2D model against the potential accuracy of a 3D one.

Despite this variety of approaches, Syvitski et al. (2010) argue the need for more accurate and faster morphodynamic models. The aim of this work is to present a novel and flexible 2D depth-averaged coupled hydrodynamic and sediment transport model developed within Thetis, a finite element coastal ocean modelling system (Kärnä et al., 2018) built using the Firedrake code generation framework (Rathgeber et al., 2017). This framework is versatile and ensures our underlying code is robust and optimised, and can be executed efficiently in parallel. Furthermore, it means our model is easily extensible and further work could include using an adjoint allowing sensitivity analyses to be conducted.
(Farrell et al., 2013) or using an adaptive mesh to further decrease computational cost (McManus et al., 2017).

In this work, a 2D model is deemed an appropriate choice because the depth-scale is much smaller than the horizontal for the cases discussed. We extend Thetis’ existing capability to model scalar transport to simulate suspended sediment transport and add within it a new capability to model bedload transport. For validation purposes, we compare our results with experimental data and Telemac-Mascaret’s 2D model (Hervouet, 1999), which is widely-used (Amoudry and Souza, 2011; Papanicolaou et al., 2008). We improve on existing state-of-the-art models by using a discontinuous Galerkin based finite element discretisation (DG) available in Thetis (Kärnä et al., 2018). DG has several advantages including being locally mass conservative, meaning sediment is conserved on an element-by-element level, which is an advantage for coupling (Dawson, Sun and Wheeler, 2004); being well-suited to advection-dominated problems (Kärnä et al., 2018); being geometrically flexible; and allowing higher order local approximations (Li, 2006). Morphodynamic models using DG have been presented in Kubatko, Westerink and Dawson (2006), Michoski et al. (2013) and Tassi et al. (2008), but without suspended sediment transport. To the best of our knowledge, our model is the first morphodynamic model with both bedload and suspended sediment transport to use DG.

The remainder of this paper is structured as follows: in Section 2 we describe our coupled hydrodynamic and sediment transport model; in Section 3 we outline details of the finite element model Thetis; in Sections 4 and 5, we use the test cases of a migrating trench and a meander to validate our model and in Section 6 we benchmark our test cases against Sisyphe.

2. Model derivation

2.1. Hydrodynamic and sediment transport equations

In this subsection, we describe the general equations for modelling the hydrodynamic and sediment transport flow, and follow the presentation and notation of Wu (2007), where more details can be found. The hydrodynamic component of the sediment-water mixture is governed by the (3D) Navier-Stokes equations for single phase flow. We use the 2D version of Thetis assuming the only external force acting on the system is gravity. We also assume any wavelength is much longer than the depth of the fluid, hence the vertical flow variation is small enough to be negligible and $\partial u_i / \partial z = \partial u_2 / \partial z = 0$ (for more details, see Segur, 2009).

The 2D model is derived by depth-averaging from the bed, $z_b$, to the water surface, $\eta$, the hydrodynamic equations. Thus, we apply the kinematic boundary condition at $\eta$ as a free moving boundary, and we consider $z_b$ to be impermeable. Since the bed evolution is slow, imposing a no-slip condition at $z_b$ means $u_1 = u_2 = 0$ here and the simplified depth-averaged equation for the conservation of mass is

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x}(\tilde{h}u_1) + \frac{\partial}{\partial y}(\tilde{h}u_2) = 0,$$

where $h = \eta - z_b$ is the depth, and $\tilde{u}_1$ and $\tilde{u}_2$ are the depth-averaged velocities in the x and y directions, respectively.

Note that following convention, depth-averaged variables are denoted with an overbar, as $\tilde{\cdot}$.

Applying the boundary conditions, combining dispersion and stress effects, and assuming no wind-driving forces on the water surface, the depth-averaged equation for the conservation of momentum is

$$\frac{\partial (\tilde{h}u_i)}{\partial t} + \frac{\partial (\tilde{h}u_i \tilde{u}_j)}{\partial x} + \frac{\partial (\tilde{h}u_2 \tilde{u}_j)}{\partial y} = -gh \frac{\partial \eta}{\partial x_i} + 1 \frac{\partial (h \tilde{\tau}_{11})}{\partial x} + 1 \frac{\partial (h \tilde{\tau}_{12})}{\partial y} - \tau_{bh},$$

where, following the notation of Wu (2007), $\tilde{\tau}_{ij} = \mu_i \left( \frac{\partial \tilde{u}_i}{\partial x_j} + \frac{\partial \tilde{u}_j}{\partial x_i} \right)$ and $\mu_i$ is the dynamic eddy viscosity. Note that $i = 1, 2$ represents the x, y-direction respectively. Eq. (1) and (2) comprise the hydrodynamic component of our model.

We take an Eulerian approach for the sediment transport equations, rather than the more computationally expensive Lagrangian approach, and make a macroscopic assumption. We thus represent the sediment dynamics via an advection-diffusion equation for a sediment concentration field, $c$. Note that in this work we only consider non-cohesive sediment.

If the sediment diameter is finer than 1 mm and the sediment concentration, $c$, is lower than 10% of the fluid volume then we can assume there is no mixing at the ‘molecular level’. Hence, there is no diffusion and the only significant relative motion between the flow and the sediment is settling due to gravity. The low concentration and fine sediment size means the settling velocity of the sediment particles $w_s$ can be approximated by that of a single sediment particle
in clear water. The equation governing the sediment concentration is

\[
\frac{\partial c}{\partial t} + \frac{\partial (uc)}{\partial x} + \frac{\partial (uc)}{\partial y} + \frac{\partial (uc)}{\partial z} = \frac{\partial}{\partial x}(u_s\delta_{31}) + \frac{\partial}{\partial y}(u_s\delta_{32}) + \frac{\partial}{\partial z}(u_s\delta_{33}).
\]  

(3)

where \(\delta_{ij}\) is the Kronecker delta applied to the vertical component. Time-averaging Eq. (3) to filter turbulence introduces a diffusivity term, \(\epsilon_s \nabla \cdot c\), and reads

\[
\frac{\partial \bar{c}}{\partial t} + \frac{\partial (\bar{u}c)}{\partial x} + \frac{\partial (\bar{u}c)}{\partial y} + \frac{\partial (\bar{u}c)}{\partial z} - \frac{\partial (w_s c)}{\partial z} = \frac{\partial}{\partial x} \left( \epsilon_s \frac{\partial \bar{c}}{\partial x} \right) + \frac{\partial}{\partial y} \left( \epsilon_s \frac{\partial \bar{c}}{\partial y} \right) + \frac{\partial}{\partial z} \left( \epsilon_s \frac{\partial \bar{c}}{\partial z} \right),
\]  

(4)

where \(\epsilon_s\) is the so-called sediment turbulent diffusivity coefficient, which can be chosen to take a larger than physically realistic value as an approximation for unresolved turbulence effects.

As bedload transport occurs along the bed and suspended sediment transport occurs across the fluid water column, the domain is conceptually divided into bedload and suspended sediment zones with an interface at \(z = z_b + \delta\) consistent with Tassi and Villaret (2014). At this interface, we define a gradient boundary condition of \(E_b = -\epsilon_s \frac{\partial c}{\partial z}|_{z=z_b+\delta} = u_s c_{bs}\) and \(D_b = \bar{u}_s c_{b}\), where \(E_b\) is the near-bed sediment erosion flux, \(D_b\) the deposition flux. As \(\delta\) is assumed to be small, following standard practice, the boundary condition is applied at \(z = z_b\). Therefore, depth-averaging Eq. (4), combining the diffusion and dispersion effects, and recalling we are modelling a long-term sedimentation process, we obtain

\[
\frac{\partial}{\partial t} \left( h\bar{c} \right) + \frac{\partial}{\partial x} \left( h\bar{u}_1 \bar{c} \right) + \frac{\partial}{\partial y} \left( h\bar{u}_2 \bar{c} \right) = \frac{\partial}{\partial x} \left[ h \left( \epsilon_s \frac{\partial \bar{c}}{\partial x} \right) \right] + \frac{\partial}{\partial y} \left[ h \left( \epsilon_s \frac{\partial \bar{c}}{\partial y} \right) \right] + E_b - D_b.
\]  

(5)

Due to the coupled nature of our model, we cannot calculate \(\bar{uc}\), but only the product of \(\bar{u}\) (from the hydrodynamic component) and \(\bar{c}\) (from the sediment transport component). These two quantities are not equal because the product of two integrated variables is not equal to the integral of their product. Thus, following Huybrechts, Villaret and Hervouet (2010), we rewrite Eq. (5) as an advection-diffusion equation for \(\bar{c}\)

\[
\frac{\partial}{\partial t} \bar{h} \bar{c} + \frac{\partial}{\partial x} \left( h\bar{u}_{adv_1} \bar{c} \right) + \frac{\partial}{\partial y} \left( h\bar{u}_{adv_2} \bar{c} \right) = \frac{\partial}{\partial x} \left[ h \left( \epsilon_s \frac{\partial \bar{c}}{\partial x} \right) \right] + \frac{\partial}{\partial y} \left[ h \left( \epsilon_s \frac{\partial \bar{c}}{\partial y} \right) \right] + E_b - D_b.
\]  

(6)

with advection velocity

\[
\bar{u}_{adv} = \frac{\bar{uc}}{\bar{c}}.
\]  

(7)

We then use a correction factor \(F_{corr} = \bar{u}_{adv}/\bar{u}\) to convert \(\bar{u}\) into \(\bar{u}_{adv}\). Continuing to follow Huybrechts, Villaret and Hervouet (2010), if we assume \(u\) has a logarithmic profile and \(c\) has a Rouse concentration profile, we obtain

\[
F_{corr} = \frac{I_2 - \log \left( \frac{B}{30} \right) I_1}{I_1 \log \left( \frac{\epsilon B}{30} \right)},
\]  

(8)

where

\[
I_1 = \int_{B-1}^1 \left( \frac{1-a}{a} \right)^R da,
\]

(9a)

\[
I_2 = \int_{B-1}^1 \log a \left( \frac{1-a}{a} \right)^R da,
\]

(9b)

with \(a = z/h, B = h/k_s\), where \(k_s = 3d_{50}\) is the grain roughness coefficient, and \(R = u_s/\kappa u_s\) the Rouse number, where \(\kappa\) the Von Kármán constant (given as 0.4 in Wu, 2007) and \(u_s\) the shear velocity. To avoid numerical integration, the Rouse concentration profile is simplified, such that Eq. (9) becomes

\[
I_1 = \begin{cases} 
\frac{1}{1-R}(1-R) & R \neq 1, \\
-\log(B) & R = 1,
\end{cases}
\]  

(10a)
\[ I_2 = \begin{cases} 
 I_1 + \log(B)B^{1-R}, & R \neq 1, \\
 -0.5(\log(B))^2, & R = 1. 
\end{cases} \quad (10b) \]

Finally, the sediment concentration equation is
\[ \frac{\partial}{\partial t}(h \tilde{c}) + \frac{\partial}{\partial x}(h F_{\text{corr}} \tilde{u}_1 \tilde{c}) + \frac{\partial}{\partial y}(h F_{\text{corr}} \tilde{u}_2 \tilde{c}) = \frac{\partial}{\partial x} \left[ h \left( \varepsilon_x \frac{\partial \tilde{c}}{\partial x} \right) \right] + \frac{\partial}{\partial y} \left[ h \left( \varepsilon_y \frac{\partial \tilde{c}}{\partial y} \right) \right] + E_b - D_b, \quad (11) \]

### 2.2. Suspended Sediment Transport

To fully describe Eq. (11), we calculate the sediment source term, \( E_b - D_b \), where \( E_b \) is the erosion flux and \( D_b \) the deposition flux. From the gradient boundary condition, we recall that
\[ E_b - D_b = w_s c_{bs} - w_s c_b = w_s c_{bs} - w_s \alpha_c \tilde{c}, \quad (12) \]

where \( w_s \) is the settling velocity of the particles, \( c_{bs} \) the equilibrium near-bed sediment concentration, \( c_b = \alpha_c \tilde{c} \) the actual near-bed sediment concentration, and \( \alpha_c \), a coefficient greater than 1 which accounts for the near-bed sediment concentration value being higher than \( \tilde{c} \) due to gravity. We choose to approximate \( \alpha_c \) using the following formula derived in Tassi and Villaret (2014),
\[ \frac{1}{\alpha_c} = \begin{cases} 
 \frac{A(1-A')}{r}, & |R - 1| > 10^{-4}, \\
 -A \log(A), & |R - 1| \leq 10^{-4}, 
\end{cases} \quad (13) \]

where
\[ r = \begin{cases} 
 \min(R - 1, 3), & |R - 1| > 10^{-4}, \\
 0, & |R - 1| \leq 10^{-4}, 
\end{cases} \quad (14) \]

\[ A = \max\left( \frac{\delta}{h}, 1 \right), \quad R \text{ the Rouse number, and } \delta \text{ the height of the bedload zone.} \]

We calculate \( w_s \) in Eq. (12) as per Van Rijn (1984), so that
\[ w_s = \begin{cases} 
 \frac{g \Delta d_{50}^2}{18 \nu}, & d_{50} \leq 10^{-4}, \\
 \frac{10 \nu}{d_{50}} \left( \sqrt{1 + 0.01 \frac{g \Delta d_{50}^2}{\nu^2}} - 1 \right), & 10^{-4} \leq d_{50} \leq 10^{-3}, \\
 1.1 \sqrt{g \Delta d_{50}}, & d_{50} > 10^{-3}, 
\end{cases} \quad (15) \]

where \( d_{50} \) is the median sediment diameter, \( \nu \) the kinematic molecular viscosity, and
\[ \Delta = \frac{\rho_s}{\rho_f} - 1, \quad (16) \]

where \( \rho_s \) is the sediment density, and \( \rho_f \) the water density.

As discussed in Garcia and Parker (1991), there are alternative formulae for \( c_{bs} \) in Eq. (12). Here we use the following formula applicable for fine sediments when no waves are present, given by Van Rijn (1984) as
\[ c_{bs} = 0.015 \frac{d_{50}}{\delta} \frac{S_0^{3/2}}{d_{50}^{3/10}}, \quad (17) \]

where \( d_a \) is the non-dimensional diameter
\[ d_a = d_{50} \left( \frac{g \Delta}{\nu^2} \right)^{1/3}, \quad (18) \]
and \( S_0 \) the transport stage parameter
\[
S_0 = \frac{\Psi \tau_b - \tau_c}{\tau_c},
\] (19)

See Tassi and Villaret (2014) for more detail. In Eq. (19), \( \tau_c \) is the critical shear stress
\[
\tau_c = (\rho_s - \rho_f) g d_{50} \theta_{cr},
\] (20)
where \( \theta_{cr} \) is the critical Shields parameter; \( \tau_b \) is the bed shear stress acting against the velocity flow and equal in magnitude in both directions
\[
\tau_b = \frac{1}{2} \rho_f C_h (\bar{u}_1^2 + \bar{u}_2^2),
\] (21)
where \( (\bar{u}_1, \bar{u}_2) \) is the depth-averaged velocity; and \( \Psi \) is the skin friction correction
\[
\Psi = \frac{C_h'}{C_h}
\] (22)
where \( C_h \) is the Nikuradse quadratic drag coefficient
\[
C_h = 2 \frac{k_s^2}{\log \left( \frac{11.036 h}{k_s} \right)^2},
\] (23)
where \( k_s \) is the Nikuradse friction height and \( C_h' \) is the Nikuradse quadratic drag coefficient using \( k_s' \) (the grain roughness coefficient defined after Eq. (9)) instead of \( k_s \). We use \( C_h' \) as the actual skin friction in our model.

2.3. Bedload transport

Following Tassi and Villaret (2014), to model bedload transport we define the bedload transport flux, \( Q_b \)
\[
Q_b = \phi_s \sqrt{g \left( \frac{\rho_s}{\rho_f} - 1 \right) d_{50}^2 \left( \cos \xi, \sin \xi \right)},
\] (24)
where \( \cos \xi = \sqrt{\frac{\bar{u}_1}{\bar{u}_1^2 + \bar{u}_2^2}} \) and \( \sin \xi = \frac{\bar{u}_2}{\sqrt{\bar{u}_1^2 + \bar{u}_2^2}} \). We choose the Meyer-Peter-Müller formula to define the non-dimensional sediment rate \( \phi_s \)
\[
\phi_s = \begin{cases} 
0, & \theta' < \theta_{cr}, \\
\alpha_{MPM} (\theta' - \theta_{cr})^{3/2}, & \text{otherwise},
\end{cases}
\] (25)
where \( \theta_{cr} \) is the critical Shields parameter, \( \alpha_{MPM} \) a coefficient equal to 8, as suggested by Tassi and Villaret (2014), and \( \theta' \) the non-dimensional Shields parameter
\[
\theta' = \frac{\Psi \tau_b}{(\rho_s - \rho_f) g d_{50}},
\] (26)
with \( \Psi \) given by Eq. (19) and \( \tau_b \) by Eq. (21).

2.3.1. Slope effect

In practice, the magnitude and direction of \( Q_b \) depends on the gradient of the bed, but this is not reflected in Eq. (24). When the bed has a positive gradient in the transport direction, gravity acts against the sediment causing the magnitude of \( Q_b \) to decrease and its direction to alter, and vice versa for a negative gradient.

(i) Magnitude correction
In correcting the magnitude we use

\[ Q_{b*} = Q_b \left( 1 - \frac{\partial z_h}{\partial s} \right), \]  

(27)
given in Soulsby (1997), where \( s \) is a direction tangential to the current and \( \Upsilon \) an empirical coefficient set to 1.3 (Tassi and Villaret, 2014).

(ii) Angle correction

Following Talmon, Struiksma and Mierlo (1995), we set

\[ T = \frac{1}{\beta_2 \sqrt{\theta}}, \]  

(28)
where \( \beta_2 \) is an empirical coefficient (equal to 1.5 for river test cases) and \( \theta \) is given by

\[ \theta = \frac{(\rho_f - \rho_s) g d_{50}}{\max \left( \frac{1}{2} \rho_f C_h \| \mathbf{u} \|, 10^{-10} \right)}, \]  

(29)
with \( C_h \) defined as in Eq. (23). Thus

\[ Q_b = \left( \phi_s \sqrt{g \left( \rho_f - 1 \right) d_{50}^3 (\cos \alpha, \sin \alpha)} \right), \]  

(30)
where \( \alpha \) is the corrected angle defined by

\[ \begin{pmatrix} \sin \alpha \\ \cos \alpha \end{pmatrix} = \frac{1}{\| \mathbf{p} \|^2} \begin{pmatrix} p_1 \\ p_2 \end{pmatrix} = \frac{1}{\| \mathbf{p} \|^2} \begin{pmatrix} \sin \xi - T \left( \frac{\partial z_h}{\partial x} \right) \\ \cos \xi - T \left( \frac{\partial z_h}{\partial y} \right) \end{pmatrix}, \]  

(31)
where \( \mathbf{p} = (p_1, p_2) \).

2.3.2. Secondary current

As illustrated in Figure 1, depth-averaged models for curved channels need to account for both the current and helical flow effects. This affects the magnitude and direction of \( Q_b \) and in Tassi and Villaret (2014) is implemented on top of slope effect corrections. Accordingly, we implement a secondary current using

\[ \tan \zeta = \frac{7 h}{r}, \]  

(32)
given in Engelund (1974), where \( \zeta \) is the angle between the bedload transport and the main flow direction, \( h \) the mean water depth, and \( r \) the local radius of curvature of the streamline calculated using

\[ r = \frac{\alpha' (u_1^2 + u_2^2)}{g \frac{\partial n}{\partial n}}, \]  

(33)
where \( \eta \) is the elevation, \( n \) a direction normal to the current and \( \alpha' \) a coefficient which lies between 0.75 (rough bed) and 1 (smooth bed).
Using Eq. (32), we construct the term
\[ \Xi = \sqrt{\left( \tau_b Y \cos \alpha + \tau_b \bar{u}_2 \tan \zeta \right)^2 + \left( \tau_b Y \sin \alpha - \tau_b \bar{u}_1 \tan \zeta \right)^2}, \]  
(34)
where \( \tau_b \) is the bedload shear stress defined by Eq. (21), and \( \alpha \) and \( Y \) are the corrected flow angle and magnitude factors (Section 2.3.1).

Hence, we define a new corrected bed transport flow direction \( \hat{a} \) with
\[ \cos \hat{a} = \frac{\tau_b Y \cos \alpha + \tau_b \bar{u}_2 \tan \zeta}{\Xi}, \]  
(35a)
\[ \sin \hat{a} = \frac{\tau_b Y \sin \alpha - \tau_b \bar{u}_1 \tan \zeta}{\Xi}, \]  
(35b)
and a new slope magnitude correction factor
\[ \hat{Y} = \frac{\Xi}{\tau_b}. \]  
(36)
Note that if a secondary current effect is imposed without slope effect corrections, then \( Y = 1 \) and \( \alpha = \bar{\xi} \), i.e. the original flow angle.

2.4. Calculating the new bedlevel
The new bedlevel, \( z_b \), is affected by both the suspended sediment and bedload transport described in Sections 2.2 and 2.3, and is governed by the Exner equation
\[ (1 - p') \frac{dz_b}{dt} + \nabla h \cdot Q_b = D_b - E_b, \]  
(37)
where \( p' \) is the bed sediment porosity. This completes the model equations.

2.5. Practical application within the Thetis framework
When implementing our model, we use two common techniques for algorithm stability and efficiency reasons.

2.5.1. Spinning up the hydrodynamics
Once the simulation starts, we are forcing a previously motionless flow, and the resulting flow instabilities could trigger unrealistic bedlevel changes. Following standard practice (e.g. Gerritsen et al., 2008), we avoid this by first running a simulation solving only the hydrodynamic equations. When the velocity and elevation fields have reached a quasi-steady state, we introduce sediment and trigger bedlevel changes.

2.5.2. Morphological scale factor
Once running a bed evolution simulation for a long period of time, a morphological scale factor, \( m \), is often used (e.g. Gerritsen et al., 2008) which increases the rate of bedlevel changes to save computational time. This factor means that each \( \Delta t \) in the hydrodynamic and sediment concentration equations is equivalent to \( m \Delta t \) for the bed evolution. We implement this by including the factor \( m \) in the Exner equation (37)
\[ \frac{(1 - p')}{m} \frac{dz_b}{dt} + \nabla h \cdot Q_b = D_b - E_b, \]  
(38)
This factor is suitable because the hydrodynamics are in an approximate steady state, and we assume throughout that changes in the bed are significantly slower than in the hydrodynamics.

3. Finite element based implementation
We build on existing elements of Thetis for the implementation of a coupled hydrodynamic and sediment transport model. Thetis is a finite element coastal ocean modelling system (built using the code generating framework Firedrake) which is first described in Kärnä et al. (2018) with a 3D model. We use the 2D depth-averaged version of Thetis outlined in Vouriot et al. (2019), which solves the shallow water equations and the non-conservation form of a depth-averaged sediment concentration equation, as discussed in the previous section.

We use a discontinuous Galerkin based finite element discretisation (DG) which has several advantages in this context, as discussed in Section 1.
3.1. DG based methods in Thetis

When using DG based methods, we generate an unstructured mesh of triangular elements tessellating our domain \( \Omega \) and define our finite element space on this mesh. Using a discontinuous function space requires the definition of variables on element edges (including on the domain boundary \( d\Omega \)), with the union of these edges denoted by \( \Gamma \). The average operator \( \{ \cdot \} \) and jump operator \( [\cdot] \) across the interior edges on scalar and vector fields are

\[
\{ \{ X \} \} = \frac{1}{2} (X^+ + X^-), \quad [\chi]_n = \chi^+ n^+ + \chi^- n^-,
\]

\[
[[X]]_n = X^+ \cdot n^+ + X^- \cdot n^-,
\]

where \( n = (n_x, n_y, 0) \) is the horizontal projection of the outward pointing unit normal on the element edge, and ‘+’ and ‘−’ denote either side of the interior edge.

3.1.1. Depth-averaged sediment concentration equation

*Thetis* uses several similar techniques to solve the hydrodynamic equations, (1) and (2), and the sediment concentration equation (11). We focus on the latter because it is the most pertinent for this work; the formulation for the hydrodynamic equations can be found in Kärnä et al. (2018), Pan, Kramer and Piggott (2019) and Vouriot et al. (2019).

To define the sediment concentration on the element edges, *Thetis* uses an upwinding scheme, \( \tilde{c} \): at each edge, \( \tilde{c} \) is chosen to be equal to its upstream value with respect to velocity, \( \tilde{c}_{\text{up}} \) (see Leveque, 1996). We discretise the sediment concentration equation (11) using the implicit Backward Euler timestepping method. The starting point for our numerical implementation is the following weak form

\[
\int_{\Omega} \psi \left( \frac{c_{i}^{(n+1)} - c_{i}^{(n)}}{\Delta t} \right) dx + \int_{\Omega} \nabla \frac{E_{i}^{(n+1)}}{\tilde{c}} \cdot (\nabla c_{i}^{(n+1)}) dx - \int_{\Omega} \nabla \cdot \left( \left( \sigma \varepsilon_{j} \nabla \tilde{c}_{i}^{(n+1)} \right) \right) dx = \int_{\Omega} \psi \left( E_{b_{i}}^{n} - D_{b_{i}}^{n} \right) dx, \tag{39}
\]

where \( \psi \) is the test function employed in the weak formulation of the finite element method. Note that as \( E_{b} \) and \( D_{b} \) are calculated explicitly using (12), the full formulation is semi-implicit.

From here several choices can be made to reach the final form used in the model. Here we choose to integrate the advection term by parts to obtain a boundary integral term, which allows us both to impose boundary conditions on our equation and to control the flux between elements on the element boundaries. Thus the weak form of the advection term becomes

\[
\int_{\Omega} \psi \tilde{c} \cdot \nabla \tilde{c} dx = - \int_{\Omega} \nabla \cdot (\tilde{c} \psi) dx + \int_{\Gamma} \tilde{c}_{\text{up}} [[\psi \tilde{c}]]_n ds. \tag{40}
\]

For the diffusivity term, we must transform the second order derivative to a first order one because we are solving our equations using a piecewise linear function space. Following Kärnä et al. (2018), we thus integrate by parts, applying the Symmetric Interior Penalty Galerkin (SIPG) method given in Epshteyn and Rivière (2007) to ensure the discretisation is stable. Thus the weak form of the diffusivity term becomes

\[
- \int_{\Omega} \psi \nabla \cdot (\varepsilon_{j} \nabla \tilde{c}) dx = \int_{\Omega} \varepsilon_{j} (\nabla \psi) \cdot (\nabla \tilde{c}) dx - \int_{\Gamma} [[\psi]]_n \cdot \{ [\psi \varepsilon_{j} \nabla \tilde{c}] \} ds + \int_{\Gamma} \sigma \{ [\varepsilon_{j}] \} [[\tilde{c}]]_n \cdot [[\psi]]_n ds. \tag{41}
\]

where \( \sigma \) is the penalty parameter of the SIPG method given in Kärnä et al. (2018).

To solve the full sediment concentration weak form equation, *Thetis* formulates the equation as a matrix problem for \( c_{\text{up}}^{(n+1)} \) and uses the generalised minimal residual method (GMRES) to solve the system (see Jacobs and Piggott (2015)). The use of upwinded numerical fluxes and slope limiters means our model is good at modelling steep bed gradients formed such as those in the migrating trench test case in Section 4 (see Kubatko, Westerink and Dawson, 2006). Furthermore, the combination of a DG based method with a semi-implicit timestepping method makes our model very robust.
3.1.2. Exner Equation

In order to avoid grid-scale noise and unstable oscillations in solving the Exner equation (37), we define the bedlevel, $z_b$, on a continuous grid, and thus use a continuous Galerkin based finite element discretisation (CG). We project all hydrodynamic and sediment transport variables from the DG space into the CG space before calculating the terms in the Exner equation. This causes a minor loss of accuracy in model variables, but overall a more stable bedlevel result. The weak form of the divergence term $\nabla h \cdot Q_b$ is

$$
\int_{\Omega} \psi \nabla h \cdot Q_b \, dx = - \int_{d\Omega} (Q_b \cdot n) \psi \, ds + \int_{\Omega} (Q_b \cdot \nabla h) \psi \, dx.
$$

(42)

Here the only boundary contribution is from the domain boundary $d\Omega$ because we are on a continuous grid and are assuming centred fluxes on interior edges. Therefore the values on either side of each interior edge cancel over the whole domain. We use the implicit backward Euler method to solve Eq. (37) allowing us to use large timesteps stably. Thus

$$
\int_{\Omega} \left(1 - \rho_i^{(n+1)} \frac{z_{b_i}^{(n+1)} - z_{b_i}^{(n)}}{\Delta t}\right) \psi \, dx = G_i^{(n+1)},
$$

(43)

where $G_i^{(n+1)}$ is the sum of the weak form of the source term (as in (39)) and (42). Note that the radius of curvature, (33), in the secondary current parametrisation is dependent on the surface elevation $\eta$ rather than on $z_b$. Hence, we rewrite $\eta$ as $(h + z_b)$ meaning we can benefit from an implicit discretisation.

4. Migrating trench test case

We consider the simple test case of a migrating trench (as in, for example, Gerritsen et al. 2008 and Van Rijn 1980) to validate the implementation of the mathematical and numerical methods used in Thetis, by using experimental data from a lab study in Van Rijn (1980) and results from Villaret et al. (2016).

In Villaret et al. (2016), for this test case, a coupled model is used comprising Telemac-Mascaret’s 2D depth-averaged hydrodynamic module, Telemac2D, and its sediment transport and bed evolution module, Sisyphe. We refer to this coupled model as Sisyphe. For the discretisation, they use Telemac-Mascaret’s continuous finite element model (Danilov, 2013) with the method of characteristics for the hydrodynamic advection terms and distributive schemes for the sediment transport advection terms. The method of characteristics has the advantage of being unconditionally stable, but is not mass conservative and is diffusive for small timesteps, meaning the problem is artificially regularised with potentially spurious mixing. Distributive schemes are mass conservative, but also have high numerical diffusion and Courant number limitations to ensure stability. For further details on both methods, see Hervouet (2007) and Tassi and Villaret (2014). The limitations of these two methods in part motivate our use of DG based methods in Thetis.

4.1. Test case configuration

In Figure 2, the initial trench profile and the final bedlevel profile after a 15 h experiment is observed demonstrating the trench migration over time.

For Sisyphe, we use the model of Villaret et al. (2016), and summarise the parameter values in Table 1. As these have been calibrated and validated by experiments, Sisyphe’s results can assist the validation of our model. Thus, we
use the same parameter values in *Thetis* on grid of mesh size $\Delta x = 0.2$ m in the $x$-direction. A coarser $\Delta y = 0.22$ m is set in the $y$-direction in our *Thetis* model than Villaret et al. (2016), who use $\Delta y = 0.11$ m. We have found that unlike in *Sisyphe*, our model results are consistent with either $\Delta y$, indicating that our model is more robust. Thus we adopt the less computationally expensive option. Finally, we use the boundary conditions from Section 2 and set the incoming suspended sediment flow rate so that the erosion flux, $E_b$, equals the deposition flux, $D_b$, at the upstream boundary. Hence, we have sediment equilibrium and the bed remains unaltered at the inlet.

4.2. Results

In this section, we run both *Thetis* and *Sisyphe* for this test case. As discussed in Section 2.5, a pure hydrodynamics simulation is run for 200 s ramping up the initial hydrodynamic conditions for our coupled simulation with bedload and suspended sediment transport. We do not use either the slope effect angle correction or secondary current here because both are superfluous in a straight channel.

Figure 2 shows that the bedlevel results from *Thetis* and *Sisyphe* agree in both magnitude and profile, but are clearly different from the experimental data. By contrast, when Villaret et al. (2016) use the parameter values in Table 1, the *Sisyphe* results agree with the experimental data. The difference between the two set-ups is the timestep, $\Delta t$: Villaret et al. (2016) use $\Delta t = 1$ s, whereas we use $\Delta t = 0.05$ s in Figure 2. This choice of $\Delta t$ is because *Thetis* requires a smaller Courant number ($U \Delta t / \Delta x$) than *Sisyphe* and for comparability reasons the same $\Delta t$ is used in both models. A possible explanation of this Courant number requirement in *Thetis* is that the overall model can be perceived as semi-implicit since all model equations are solved implicitly (or semi-implicitly for the sediment concentration equation), while the coupling of the hydrodynamic and sediment transport components is explicit.

Figure 2 also illustrates that using either a morphological scale factor of 10 or 1 in our *Thetis* model gives very similar results. Unless otherwise stated, all figures in this section are produced using a morphological scale factor of 10. Although *Sisyphe* has an option for a morphological scale factor, it is not imposed in this work in *Sisyphe* because neither Villaret et al. (2016) or Villaret et al. (2013) apply it.

4.2.1. Sensitivity study

The dependence of *Sisyphe*’s results on $\Delta t$ presents a necessity for a sensitivity study on the robustness of the models to small changes in physical parameters, timestep and/or mesh step size. First, we explore the impact of varying $\Delta t$ and the mesh size $\Delta x$ on the final bedlevel. Note that once the mesh size $\Delta y$ is small enough that the results are smooth in *Sisyphe*, it has no effect because there is negligible bedlevel variation in that direction. Figure 3a shows that the *Sisyphe* bedlevel results vary significantly with $\Delta t$. Only when $\Delta t = 1$s, the value of Villaret et al. (2016), is there a good agreement between *Sisyphe* and the experimental data. As $\Delta t$ decreases, *Sisyphe*’s results converge to the same result as *Thetis* in Figure 2. By contrast, bedlevel results from *Thetis* are largely insensitive to changes in $\Delta t$, as seen in Figure 3b.

Furthermore, we run a small study to investigate whether *Sisyphe* is always sensitive to $\Delta t$ for this test case. When the method of characteristics is chosen for the hydrodynamics, as in Villaret et al. (2016), we find *Sisyphe* is always sensitive to $\Delta t$, independent of the choice of morphodynamic scheme. Other methods for the hydrodynamics have stricter Courant number criteria, requiring $\Delta t < 0.01$ s to run (even smaller than our *Thetis* value), meaning this effect

**M. C. A. Clare et al.**
We also run a sensitivity study for $\Delta x$ and find that for finer meshes than that used in Villaret et al. (2016), both models were insensitive to $\Delta x$ (see Figures 3b, 3c and 3d). However, one of the advantages of the DG method is that it is good at dealing with sharp gradients. To illustrate this we run the test case with a significantly coarser mesh of $\Delta x = 0.5m$. Thus in the $x$-direction, each side of the trench is initially represented by three mesh elements and the flat bottom of the trench is initially represented by six mesh elements. The mesh nodes are located exactly at the vertices of the slope, meaning that the initial geometry is accurately represented by this mesh. Figure 4b shows that for our Thetis model there are no observable differences between the coarser and finer meshes. On the other hand, Figure 4a shows that Sisyphe fails to produce an accurate solution. Due to instabilities, the Sisyphe solution has also broken symmetry in the $y$-direction meaning that it is no longer independent of $y$, indicating Sisyphe has not converged accurately. To show the solution’s dependence on $y$, in Figure 4a, we show the final bedlevel transects at the beginning ($y = 0.0m$), midpoint ($y = 0.55m$) and end ($y = 1.1m$) of the domain (recall that in Sisyphe, $\Delta y = 0.11m$). By contrast in Figure 4b, as in the other figures in this section, we only need to show the transect at the midpoint because the solution from our model is effectively independent of $y$.

Given the robustness of Thetis from this point onwards all our model results for the migrating trench test case apply $\Delta x = 0.5m$ and $\Delta t = 0.6s$. Given the lack of robustness in Sisyphe from this point onwards all our Sisyphe model results for the migrating trench test case use $\Delta t = 0.01s$.

For small values of $\Delta t$, Thetis and Sisyphe are consistent. We conjecture that the errors caused in Sisyphe with larger $\Delta t$ values manifest themselves as an increase in effective diffusivity in the model. We thus conduct a sensitivity study for $\Delta x$ and $\Delta t$. For small values of $\Delta t$, Thetis and Sisyphe are consistent. We conjecture that the errors caused in Sisyphe with larger $\Delta t$ values manifest themselves as an increase in effective diffusivity in the model. We thus conduct a sensitivity study for $\Delta x$ and $\Delta t$.
study for the sediment turbulent diffusivity coefficient, $e_s$. For this study, we choose $\Delta t = 0.01$ s in Sisyphe. Bedlevel results from both Sisyphe and Thetis in Figures 5a and 5b show they are indeed greatly affected by $e_s$ and, importantly, that both models behave consistently. Note that, due to stability constraints, Sisyphe does not run with $e_s > 0.2$ m$^2$ s$^{-1}$, unlike Thetis. The observed sensitivity to $e_s$ is to be expected because the grid Peclet number ($U \Delta x / e_s$) decreases with $e_s$, making diffusion the key driver of the sediment concentration equation, rather than advection. Thus, we can use $e_s$ to calibrate both models; in Sisyphe, $\Delta t$ can be used to similar effect. If we set $e_s = 0.15$ m$^2$ s$^{-1}$, Thetis and Sisyphe’s converged results agree well with each other and with the experimental data, as shown clearly in Figure 6. Thus, we have validated Thetis for this simple test case.

5. Meander test case

Our second test case regards the curved channel of a meander, which requires and demonstrates the implementation of a slope affect angle correction and a secondary current. This test case is used to validate these additional functionalities, and affirm our model can handle more complex and realistic set-ups.

5.1. Test case configuration

We use the configuration from experiment 4 from Yen and Lee (1995) and validate Thetis through the experimental data and Sisyphe results from Villaret et al. (2013). Most of the bed changes occur at the boundary so, following Villaret et al. (2013), we use a finer mesh there (0.1 m) and a coarser one (0.25 m) along the centre of the channel, as in Figure 7.

We impose time dependent flux and elevation boundary conditions reproducing Yen and Lee (1995). The initial inflow flux and outflow elevation are 0.02 m$^3$ s$^{-1}$ and 0 m, respectively. Both increase linearly until reaching their respective maximums of 0.053 m$^3$ s$^{-1}$ and 0.103 m at 100 min, and then decrease linearly to their initial values at 5 h.

We also impose a free-slip condition on the meander boundary walls.

In both Thetis and Sisyphe, we use the parameter values summarised in Table 2. Following Villaret et al. (2013), we only model bedload transport because this is the principal sediment transport component in rivers. Hence, we do not need to specify the diffusivity coefficient $e_s$. The implementation of the secondary current requires we determine the flow roughness to set the value of $a'$ in Eq. (33). Following Kulkarni and Sahoo (2013), we calculate that the roughness Reynolds number, defined by $(k_s \sqrt{\tau_b})/ (\nu \sqrt{\rho_f})$, is approximately 80, and conclude we are in a rough turbulent flow regime. Consistently with Tassi and Villaret (2014), we use $a' = 0.75$.

5.2. Results

5.2.1. Modelling the hydrodynamics

If we use the same viscosity value when modelling the hydrodynamics for the meander test case as for the migrating trench test case ($1 \times 10^{-6} m^2 s^{-1}$), we find that our model does not accurately solve the flow at the meander boundary walls. Instead of finding a smooth solution, the flow magnitude increases dramatically in cells closest to the boundary. However molecular viscosity values ($1 \times 10^{-6} m^2 s^{-1}$) only become relevant at the Kolmogorov scale. Our test case is at a much larger scale where viscous turbulence forces exist. As such the viscosity is accounting for the turbulence or eddy viscosity and a value of $1 \times 10^{-3} m^2 s^{-1}$ (the value by Vouriot et al. (2019) for their Thetis test case) is more appropriate. As we increase $\nu$ in the hydrodynamic equations (1) and (2) the flow becomes smoother and for viscosity values of $O(1 \times 10^{-3})$ the boundary issue no longer exists. The issue itself is related to how boundary conditions at closed impermeable boundaries are imposed in equal order DG discretisations and will be addressed in the future.

As we are not using a turbulence model, to find the correct value of $\nu$, we use Sisyphe’s hydrodynamic results to calibrate our model, noting that Villaret et al. (2013) use $1 \times 10^{-2} m^2 s^{-1}$. These alterations in $\nu$ change the nature of the test case, but can be balanced by altering the longitudinal bed slope. In Yen and Lee (1995), the meander has a longitudinal bed slope of 0.002, as in Villaret et al. (2013). We find that for a longitudinal bed slope of 0.0035 and $\nu$ of 0.035 m$^2 s^{-1}$, our model’s velocities match those in Sisyphe reasonably well, as shown in Figures 8a and 8b. These figures also show that even with time dependent boundary conditions, using a morphological scale factor equal to either 1 or 10 in Thetis gives equivalent results. Thus, unless otherwise stated, in this section our Thetis results are produced with a morphological scale factor of 10.
5.2.2. Modelling sediment transport

As the hydrodynamics of Thetis agree with Sisyphe, we introduce sediment transport into the models. As discussed in Section 2.5, initially a simulation for 200 s solves only the hydrodynamics with a fixed flux inflow of 0.02 m³ s⁻¹ and outflow elevation of 0 m. For our full sediment transport simulation, we use these results as initial flow conditions and impose time dependent flux and elevation conditions from Section 5.1 as the boundary conditions. We present the scaled bedlevel evolution results, defined as

\[
\text{Scaled Bedlevel Evolution} = \frac{z_{\text{final}} - z_{\text{initial}}}{z_{\text{initial}}}
\]

(44)

where \(z_{\text{final}}\) is the final bedlevel after 5 h and \(z_{\text{initial}}\) is the initial bedlevel of −0.0544 m.

Figure 9 shows the effects of implementing secondary current and slope effects on the bedlevel evolution at the meander outflow. The slope effect magnitude correction has little effect compared to the secondary current and slope effect angle corrections, likely because the slopes in this test case are fairly gentle.

In Figure 9d, the final scaled bedlevel evolution result is shown, with erosion at the outer bend and deposition at the inner bed, as expected from physical intuition. Comparing this figure with Figure 10 from Villaret et al. (2013), we see Thetis result has the same distribution and magnitude as the experiment and Sisyphe. Hereafter, unless otherwise stated that the results are from the present study, Sisyphe results are taken from those presented in Villaret et al. (2013).

To compare our Thetis result with the experiment and Sisyphe’s results more accurately, we take a cross-section at the 90° and 180° angles marked on Figure 10. Figures 11a and 11b shows our model reproduces the experimental results better than Sisyphe, with a particular improvement at the 180° cross-section and the bedlevel erosion at both cross-sections.

Figure 8: Minimum and maximum velocities from Thetis (\(v = 0.035 \text{ m}^2 \text{s}^{-1}\), slope = 0.0035) with a morphological scale factor of 1 and 10, and Sisyphe, present study, (\(v = 0.01 \text{ m}^2 \text{s}^{-1}\), slope = 0.002).

5.2.3. Calibration study

In Section 5.2.1, we used the hydrodynamic results from Sisyphe to calibrate the viscosity and longitudinal slope in Thetis in the absence of observed data. However, Figures 11a and 11b show Sisyphe does not agree completely with the experimental data. Hence, to improve our model’s accuracy, we re-run the calibration study using the experimental data as the ‘real solution’. We seek to minimize the relative error norm at both the 90° and 180° cross-section and thus minimise

$$
\left( \frac{\|y_{90} - \hat{y}_{90}\|_2}{\|y_{90}\|_2} \right)^2 + \left( \frac{\|y_{180} - \hat{y}_{180}\|_2}{\|y_{180}\|_2} \right)^2,
$$

where $\hat{y}_{90}$ is the experimental data and $y_{90}$ our model result. The results are summarised in Table 3 and show that a viscosity of 0.05 m² s⁻¹ and a longitudinal slope of 0.0035 yield the best approximation to the experimental data. To ensure that by using (45) we are not merely reducing the error at one cross-section whilst allowing the error at the other cross-section to grow, we also calculate the following maximum norm

$$
\max \left( \frac{\|y_{90} - \hat{y}_{90}\|_2}{\|y_{90}\|_2}, \frac{\|y_{180} - \hat{y}_{180}\|_2}{\|y_{180}\|_2} \right),
$$

and summarise the results in Table 4. Although $v = 0.05 \text{ m}^2 \text{s}^{-1}$ and a longitudinal slope of 0.0035 do not minimize Eq. (46), they result in one of the smallest maximum error norms. Comparing Figures 11 and 15, we can confirm that
Table 4

</tr>
</tbody>
</table>

Using these new values of \( v \) and longitudinal slope result in a better approximation to the experimental data.

Using a viscosity of 0.05 m² s⁻¹ and a longitudinal slope of 0.0035, Figure 12 shows that the scaled bedlevel evolution from Thetis agrees closely with the experiment, particularly at the inner bend and at the meander outflow. Comparing the experiment, Sisyphe (Figure 10) and our results (Figure 12), we see that Thetis predicts the bedlevel erosion to a greater degree of accuracy, particularly at the outer bend. Furthermore, it shows uniform erosion at the inflow bedlevel, unlike Sisyphe (Figure 10), although neither model predicts the inflow bedlevel particularly accurately.

For rigour, we run Sisyphe with these optimised values for viscosity and longitudinal slope. The resulting bedlevel change is shown in Figures 13a and 13b at the 90° and 180° cross-sections, respectively. There is a marginal improvement in the total relative error norm (45), which falls from 1.144 for the results from Villaret et al. (2013) to 1.067 for the optimised values. However, the errors of Sisyphe are still higher than those obtained for Thetis.

5.2.4. Sensitivity Study

Given Sisyphe’s sensitivity to \( \Delta t \) discussed in Section 4.2.1, we conduct a sensitivity study on \( \Delta t \) and \( \Delta x \), maintaining a ratio between fine and coarse meshes at 2:5. We configure Sisyphe ourselves and use our optimised viscosity and longitudinal slope values for consistency with Thetis.

Thetis is insensitive to \( \Delta t \) (Figure 14b), whereas Sisyphe (Figure 14a) is sensitive to \( \Delta t \), as in the migrating trench test case. Although for \( \Delta t \leq 0.25 \) s Sisyphe’s results are robust, for larger \( \Delta t \) values they are both sensitive and inaccurate. Furthermore, for this test case, Thetis converges for \( \Delta t < 10 \) s, meaning it is much less computationally expensive than Sisyphe, which requires \( \Delta t \leq 0.25 \) s.
Both models are relatively insensitive to the mesh step size \( \Delta x \) (Figures 14c and 14d). There are slight differences when a fine \( \Delta x = 0.25 \) m is used in both models, suggesting our fine \( \Delta x = 0.1 \) m is appropriate.

As in Section 4.2, we assess whether Sisyphe results depend on the discretisation of the advection terms. Our preliminary results show that Sisyphe’s sensitivity to \( \Delta t \) is independent of the choice of morphodynamic scheme, as indicated in the previous example. The strict Courant number stability criteria of other Sisyphe hydrodynamic discretisations means they require small \( \Delta t \) to run and thus the effect is less noticeable.

Finally, Figures 15a and 15b provide an overview of our results and show not only that we have validated our model, but that it is more accurate than Sisyphe for this more complex test case. Figures 15a and 15b also confirm that a morphological scale factor of 10 is appropriate with no observable difference between a morphological scale factor of 10 and 1 (i.e. no scaling).

### 6. Benchmarking

Finally, we compare the computational times and error norms of Thetis and Sisyphe for both test cases discussed and summarise results in Table 5. For Sisyphe we have chosen the most efficient matrix storage method following guidance by Lang et al. (2014). We find that for the more complex geometry of the meander, our model using the same mesh is approximately twice as accurate as Sisyphe. For the migrating trench, we find that Sisyphe is more accurate than our model. However, this is only true for this specific choice of mesh resolution and timestep in Sisyphe. As the timestep increases and the mesh becomes coarser, the accuracy of the Sisyphe result is found to decrease (see Figure 15).
Table 5
Comparison of computational time, $t_s$ (seconds) (left) and L2 error norm to data (right) with a morphological scale factor. For the migrating trench, $\Delta t = 0.01$ s and $\Delta x = 0.2$ m in Sisyphe and $\Delta t = 0.6$ s and $\Delta x = 0.5$ m in Thetis; for the meander $\Delta t = 0.1$ s in Sisyphe and $\Delta t = 2$ s in Thetis and a fine $\Delta x = 0.1$ m in both.

</table>

The robustness advantages observed with Thetis’s DG-based discretisation delivers accurate results with both larger $\Delta t$ and $\Delta x$ values. Without using a morphological scale factor, Thetis is slower, partly since on the same mesh a DG discretisation possesses significantly more degrees of freedom. However, the added robustness means we are able to readily apply a morphological scale factor to reduce computational times without compromising accuracy. Table 5 presents the accuracy and efficiency results of applying a morphological scale factor. It shows that with a morphological scale factor of 50, the meander test case is two times more efficient than Sisyphe and the migrating trench test case is ten times more efficient, whilst retaining accuracy in the obtained results.

7. Conclusion

In this work, we have presented a new 2D depth-averaged coupled hydrodynamic and sediment transport functionality within the finite element based coastal ocean model Thetis. Our model makes significant, novel contributions to the complex problem of modelling sediment transport. It is shown to be accurate, as well as more efficient and stable than other standard models. To the best of our knowledge, it is the first full morphodynamic model employing a DG based discretisation. We report on several new capabilities within Thetis, including bedload transport, bedlevel changes, slope effect corrections, a secondary current correction, a sediment transport source term, a velocity correction factor in the sediment concentration equation, and a morphological scale factor. All these were validated using the migrating trench and meander test cases, indicating the significance of each of the additional components. The coupled and nonlinear nature of the problem makes this type of model very sensitive to parameter changes. However, Thetis is found to be largely insensitive to changes in timestep and mesh grid size, unlike the current state-of-the-art model Sisyphe, which is found to have a much larger variability, particularly with respect to the timestep in the case of the test cases considered in this work. The robustness of Thetis enables the application of a morphological scale factor for computational efficiency relative to existing models, whilst remaining accurate.

In future work, we will use our model in a coastal zone case study requiring coupled wave and current modelling. We will also use the advantages of the adjoint capabilities of Thetis to perform adjoint-based model calibration on our hydro-morphodynamic model, improving the accuracy of our model.

Acknowledgements

The authors thank Dr Catherine Villaret for her help in the set-up of Sisyphe. MCAC’s work was funded through the EPSRC CDT in Mathematics for Planet Earth. AA acknowledges the support of NERC through the fellowship grant NE/R013209/2. MDP, JRP and CJC acknowledge the support of EPSRC through the grants EP/R029423/1 and EP/R007470/1.
