21

22 Abstract

23 Dendroarchaeology almost exclusively uses ring-width (RW) data for dating historical structures
24 and artefacts. Such data can be used to date tree-ring sequences when regional climate dominates RW
25 variability. However, the signal in RW data can be obscured due to site specific ecological influences
26 (natural and anthropogenic) that impact crossdating success. In this paper, using data from Scotland, we
27 introduce a novel tree-ring parameter (Blue Intensity – BI) and explore its utility for facilitating dendro-
28 historical dating of conifer samples. BI is similar to latewood density as they both reflect the combined
29 hemicellulose, cellulose and lignin content in the latewood cell walls of conifer species and the amount of
30 these compounds is strongly controlled, at least for trees growing in temperature limited locations, by late
31 summer temperatures. BI not only expresses a strong climate signal, but is also less impacted by site
32 specific ecological influences. It can be concurrently produced with RW data from images of finely sanded
33 conifer samples but at a significantly reduced cost compared to traditional latewood density. Our study
34 shows that the probability of successfully crossdating historical samples is greatly increased using BI
35 compared to RW. Furthermore, due to the large spatial extent of the summer temperature signal expressed
36 by such data, a sparse multi-species conifer network of long BI chronologies across Europe could be used to
37 date and loosely provenance imported material.

40 Tree-ring dating; dendroarchaeology; Blue Intensity; conifers

41

42 1. Introduction

43 Dendrochronology is multidisciplinary in nature and has many applications in the environmental
44 sciences including ecology, geomorphology and climatology (Schweingruber 1996; Hughes et al. 2010;
45 Speer 2010; Stoffel et al. 2010). The common fundamental keystone to all dendrochronological sub-
46 disciplines is the ability to ensure exact calendar dating of the tree-ring (TR) series. Crossdating is the ability
47 to pattern-match or synchronise TR sequences between samples of the same species across a climatically
48 homogenous region to allow the identification of the exact year in which a particular TR was formed
49 (Stokes and Smiley 1968; Fritts 1976). One of the earliest uses of dendrochronological methods was the
50 dating of historical structures and artefacts (so-called dendroarchaeology) and a large body of published

51 work now exists detailing the development of this sub-discipline (Baillie and Pilcher 1973; Baillie 1982;
52 Pilcher et al. 1984; Kuniholm 2001).

53 Until now, dendroarchaeology has almost exclusively utilised ring-width (RW) as the main tree
54 growth variable for crossdating. RW is inexpensive to produce, not only directly from samples (via
55 microscope graticules or measuring stages), but can also be measured from sample casts (Crone 2008),
56 photographs (Mills 1988; Levanič 2007) and scanned images (Rydval et al. 2014). The success of
57 dendroarchaeology from many regions across both the Old (Baillie 1995; Kuniholm & Striker 1987; Manning
58 & Bruce 2009) and New (Douglass 1929; Nash 1999) Worlds highlights the importance of this variable for
59 historical dating.

60 Crossdating is possible because trees of the same species within the same region respond in a
61 similar way to climate. This means that during years of favourable growth conditions, all trees, on average,
62 will develop a relatively wide ring, whereas thinner rings will develop when environmental conditions are
63 less favourable. RW patterns, therefore, can be synchronised between trees in the same area and the
64 strength of the common signal between trees and across wide regions often reflects the strength of the
65 climatic influence on growth.

66 The sensitivity of tree-growth to climate is a function of the tree's geographical location which
67 influences what aspect of climate most limits tree productivity. As a general rule, in high latitude/altitude
68 situations, growth is limited by summer temperatures, whereas at low latitude/altitude sites, tree-growth is
69 more commonly limited by moisture availability. Many transect and regional network studies have shown
70 this change in general tree response to climate with elevation and/or latitude (Fritts et al. 1965; LaMarche
71 1974; Ling 1986; Kienast et al. 1987; Wilson and Hopfmueller 2001; Babst et al. 2012; St George 2014). In
72 regions of complex topography, however, the varying response of tree-growth to climate for a single
73 species can complicate between-site crossdating and dendroarchaeological dating. For example, Wilson et
74 al. (2004) showed for the Bavarian Forest in Germany, that when using RW, low elevation moisture limited
75 Norway spruce trees (< 700 m.a.s.l.) could not be crossdated with high elevation temperature sensitive
76 trees above 1100 m.a.s.l despite these two regions being only about 50km apart.

77 An additional limiting factor influencing the utility of RW for dendroarchaeology is that RW
78 variability is an aggregated product of multiple environmental factors (e.g. climate, site ecology, natural
79 and anthropogenic disturbance, etc.) influencing tree-growth throughout the year (Cook 1985). From a
80 dating perspective, it is desirable for the common regional scale climatic influence upon growth to
81 dominate the variability in RW series and the impact of local factors (natural and anthropogenic) to be
82 minimal. Optimising the climatic influence expressed in TR series and minimising the "noise" of all other
83 factors therefore facilitates crossdating. This is strategically performed through careful site selection in
84 dendroclimatological studies (Fritts 1976), but for dendroarchaeology, the exact provenance of historic
85 timbers may never be ideal to optimise the climatic influence expressed by RW data and so the climate
86 related signal is often weaker with resultant detrimental implications for dating.

87 RW is not the only variable that can be measured from tree rings however. Density based
88 parameters (Polge 1970; specifically maximum latewood density) have been successfully used over the last
89 30 years as an effective proxy of past summer temperatures (Briffa et al. 1992, 2001; Wilson and Luckman
90 2003; Esper et al. 2012; Schneider et al. 2015). Stable isotopes, in recent years, have also been shown to
91 provide additional information expressing a whole new swath of climatic information that can be extracted
92 from TR samples (McCarroll and Loader 2004; Treydte et al. 2007; Young et al. 2015). However, measuring
93 ring density or stable isotopes requires specialised equipment (which few TR laboratories possess) and are
94 much more expensive to produce compared to RW.

95 A novel TR variable that has been championed for dendroclimatology in recent years is Blue
96 Intensity (BI - McCarroll et al. 2002; Björklund et al. 2014; Rydval et al. 2014; Wilson et al. 2014). BI is
97 similar to maximum latewood density (MXD) as they both essentially measure the combined hemicellulose,
98 cellulose and lignin content (related to cell wall thickness) in the latewood of conifer trees. The intensity of
99 the light reflectance in the blue part of the spectrum is a good proxy of the amount of these compounds
100 (especially lignin) and cell wall thickness as they readily absorb blue light. Therefore, dense, darker

101 latewood will result in less reflected blue light. BI and MXD are therefore related (inversely correlated) and
102 have been shown to express a much stronger relationship with summer temperatures than RW as they
103 express a “purer” climate signal and are less influenced by other site specific non-climatic factors (Björklund
104 et al. 2014; Rydval et al. 2014; Wilson et al. 2014). BI data can be generated at the same time as RW data at
105 no additional cost by measuring directly from images (scans or photographs) of finely sanded conifer wood
106 samples and can theoretically be generated by any dendrochronological laboratory with minimal
107 investment (see Campbell et al. (2011); Rydval et al. (2014) and Österreicher et al. (2015) for different
108 approaches for BI measurement). As BI generally expresses a stronger summer temperature signal than
109 RW, at least at inter-annual time-scales (Rydval et al. 2014, 2016b; Wilson et al. 2012, 2014) and is less
110 susceptible to site specific ecological “noise”, we hypothesise that the use of BI will substantially improve
111 our ability to successfully date historical structures where conifer wood is the main construction material.

112 In this paper, we present the first exploration of using BI data to aid dendro-historical dating using a
113 Scottish case study. In Scotland, the dendrochronological dating of imported archaeological oak using RW
114 has been reasonably successful, aided by a network of reference chronologies across northern Europe
115 (Crone and Mills 2012). However, dating native timber is less straightforward, in part due to chronological
116 and geographical gaps in native reference chronologies (Mills and Crone 2012). Using just RW data,
117 historical dating of native pine in Scotland has been an especially formidable challenge (Crone and Mills
118 2002; 2011) and until recently only a few structures, built with local pine, had been dated (Mills and Crone
119 2012). While in part this is related to the need for the development of a network of native pine reference
120 chronologies (Mills 2008) it also appeared to be related to intrinsic characteristics of pine used in Scottish
121 buildings, including the predominant use of young (< 80-year) timbers, which make dating more difficult
122 (Crone and Mills 2011; Mills and Crone 2012). BI has changed this situation substantially, and its use has
123 significantly increased the chance of attaining a robust date for historical structures – whether the conifer
124 construction material was sourced in Scotland or from other regions in Europe.

125 This paper first details the current status of the Scottish pine TR network and the defined regional
126 reference chronologies used for historical dating. The dating potential of BI versus RW is then examined
127 using four independently sampled living sites and six historical structures. A sub-sampling exercise, using
128 the full Scottish pine data-set, is then performed to model how many timbers would theoretically need to
129 be measured and dated from a historical phase/structure to “guarantee” a successful crossdate using either
130 RW and BI. The paper ends by examining the wider implications of using BI data for crossdating and
131 provenancing across Europe in light of the significant amount of trade and transportation of conifer
132 construction material over the last 500 years throughout the whole region.

133

134 **2. Data and Methods**

135 The current network of Scots pine chronologies, developed as part of the Scottish Pine Project
136 (<https://www.st-andrews.ac.uk/~rjsw/ScottishPine/>), includes 44 sites of which BI data have been
137 measured from 20 (Rydval et al. 2016b; Figure 1). For historical dating purposes, the individual site data
138 have been pooled to create five regional reference series to maximise replication and common signal and
139 minimise site specific noise. The North-West (NW – AD 1621-2013), South-West (SW – AD 1508-2011) and
140 Southern Cairngorm (SC– AD 1477-2012) regional reference series are derived entirely from living trees
141 while West-Central (CNT – AD 1260-2013) and the Northern Cairngorms (NC – AD 1089-2013) have been
142 extended using preserved sub-fossil material collected from near-shore shallow lake sediments (Wilson et
143 al. 2012; Rydval et al. in review-a). The data from all five regions were also combined to create the Scottish
144 Mega Master (SMM).

145 Sample replication for each regional reference series decreases back in time (supplementary Figure
146 1) with associated weakening in the expressed population signal (EPS) strength statistic (Wigley et al. 1984).
147 EPS is an empirical metric commonly used in dendroclimatology to assess how well a sample chronology of
148 finite replication represents the theoretical infinitely replicated population chronology. It is derived using
149 the following equation:

150

151 EQ1:

152

$$EPS = \frac{n \bar{r}}{n \bar{r} + (1 - \bar{r})}$$

153

154 where n is the number of TR series and \bar{r} (often referred to as RBAR) is the mean inter-series correlation of
155 all possible detrended bivariate pairs of TR series in a chronology. RBAR is a measure of the common signal
156 between the TR series and the EPS values can be interpreted as the squared correlation between the
157 sample chronology and the theoretical population chronology. Values > 0.85 are often cited as adequate
158 for dendroclimatological purposes (Wigley et al. 1984). All analyses in this paper are focussed on the post
159 1700 period where EPS is > 0.85 for most regional reference series (supplementary Figure 1). The above
160 equation can be re-arranged to predict how many TR series would be needed to attain an EPS of a certain
161 value (i.e. 0.85) for a given empirically estimated chronology RBAR value:

162

163 EQ2:

164

$$n = \frac{(\bar{r} - 1)EPS}{\bar{r}(EPS - 1)}$$

165

166 Comparison of the dating potential of BI versus RW was performed using data from; (1) four living
167 sites (Figure 1 and Table 1) that were used as historical “analogues”, where sample provenance is known,
168 and (2) data from six historical sites (Figure 1 and Table 2), where the original growth location of the
169 timbers is unknown but presumed to be local to the sampled structure. Although the data for the living
170 sites come up to present, the recent end of the RW and BI time-series was truncated to create site
171 chronologies with a mean sample length (MSL) of ca. 80 years to create “analogue” chronologies that
172 represent the mean sample length often observed from samples taken from historical structures in
173 Scotland (Table 2). It should be noted that the six test historical sites represent data measured from
174 samples that have been successfully dated using both RW and BI. Many samples from each of these
175 structures have not been successfully dated mainly due to short sequences, fragmented samples or
176 substantial worm related decay (Table 2).

177 The RW and BI data for the regional reference series and test sites were detrended via 1st
178 differencing and the individual transformed series averaged to create regional and site chronologies. 1st
179 differencing removes all low frequency variability in the TR series (reducing 1st order autocorrelation) and
180 allows crossdating to be performed using only the inter-annual signal. The chronologies for each TR variable
181 were correlated with each regional reference chronology and the associated T-value (Baillie and Pilcher
182 1973) calculated to assess the significance of the crossdate. The T-value, commonly used in European
183 dendroarchaeology, essentially transforms the correlation between two time-series to a probabilistic value
184 following the Student T-distribution using the following equation:

185

186

187

188 EQ3:

189

$$T = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}$$

190

191 where n is the number of years in the period of overlap and r is the Pearson’s correlation value between
192 the two time-series. A T-value > 3.5 is often used as a minimum threshold to identify a significant crossdate
193 but herein we use a value of 4.0 as a more conservative acceptance threshold.

194 To model the theoretical number of TR series needed to acquire a “robust” crossdate, a
195 bootstrapped sub-sampling exercise, for both RW and BI, was performed using the full SMM data-set.
196 Random sample chronologies (from 1 TR series up to 20 TR series) were extracted from the full SMM data-
197 set (performed using the 1721-1800 and 1821-1900 periods) and the correlation between each random

198 sub-sample mean chronology and the mean of the remaining series calculated. For each replication step,
199 this random sub-sampling was performed 1000 times allowing an estimate of the range in correlation
200 values for each incremental increase in n .

201 Finally, to examine the potential utility of using BI to facilitate crossdating of historical material
202 from various conifer species with unknown provenance from regions around Europe, RW, BI (Scotland,
203 Sweden, the Alps) and MXD (Sweden, the Alps and the Pyrenees) chronologies were used to examine the
204 spatial climatic fingerprint of each of these TR variables. The BI data were inverted to exhibit the same
205 positive correlation relationship with temperature displayed by the MXD data.
206

207 **3. Results and Discussion**

208 **3.1 Chronology metrics**

209 Table 1 details meta information for the four living “analogue” test sites while their locations are
210 shown in Figure 1. Ryvoan (RYV) and Loch an Eilein (LAE) are located in the core pine woods of the northern
211 Cairngorms, the latter area being chosen as there is a strong history of human felling related disturbance
212 (Rydval et al. 2016a) which might affect the ability to crossdate tree samples taken from these woods. Glen
213 Orchy (GOS) is located on the south-western edge of the Scottish pine network while Loch Coldair (LCL), an
214 abandoned 19th century plantation, is situated in what we refer to as “the network hole” where no semi-
215 natural pine woodlands exist today. The RBAR values for RW vary from 0.26 (LAE) to 0.34 (GOS and LCL)
216 with a mean of 0.31, while values are generally higher for BI ranging from 0.27 (GOS) to 0.46 (RYV) with a
217 mean of 0.40 (Table 1). Using Equation 2, on average about 13 trees are needed to attain an EPS of 0.85 for
218 RW, while only 9 trees are needed using BI. Examining the same metrics for the six historical sites (Table 2)
219 identifies a similar range for RW (0.25-0.49; mean = 0.36) and BI (0.27-0.46; mean = 0.36). Statistically,
220 there is no difference between the overall RBAR values for RW and BI between the living and historic sites
221 (Tables 1 and 2) and 11 trees would be needed to attain an EPS > 0.85 in both cases.

222 Low RBAR values can reflect either (1) non-climatic influences on tree-growth which could explain
223 the lower values for LAE or (2) mixed assemblages of timbers reflecting different source areas for the
224 historical timbers. Although BI reflects a stronger climate signal than RW (Wilson et al. 2012; Rydval et al.
225 2016b), the quality of the reflectance data can be impacted by discoloration (e.g. due to algal staining and
226 decay), sample integrity (i.e. worm holes) and/or the presence of reaction wood, resulting in lower RBAR
227 values. Overall, however, the signal strength metrics of the six historical sites are generally similar to those
228 seen for the living analogue sites, although this is perhaps not surprising as these data represent samples
229 which have been successfully dated. The signal strength analysis for both groups (Tables 1 and 2) indicate
230 that the actual replication in the dated historical samples is often lower than needed to attain an EPS of
231 0.85. This is not a problem *per se*, but does hint that crossdating against the regional reference
232 chronologies would improve if site/phase chronology replication was higher (see later discussion).
233

234 **3.2 Crossdating results**

235 The T-values for each of the four living “analogue” sites against the five regional reference
236 chronologies and the SMM (Figure 2) show that BI is clearly superior to RW for crossdating the living pine
237 chronologies. In all cases, and compared with all regional reference series, T-values using BI are
238 substantially higher than 4.0 and many values are > 10. For RW, the crossdating results are much weaker
239 and more variable. RYV, LAE and GOS still, however, yield significant dating results with the regional
240 reference series from where the trees were actually located. LCL shows marginally stronger results with the
241 Northern Cairngorms – the geographically closest regional reference data-set. Both GOS and LCL show
242 reasonably strong T-values using RW against all regional records. This observation might reflect the higher
243 replication (and stronger signal strength, Table 1) of these two sites compared to RYV and LAE. Weakest
244 crossdating results are noted for the LAE site using RW affirming the weak signal strength results (Table 1)
245 as well as the “muddying” effect of the signal related to known felling related disturbance (Rydval et al.
246 2016a). Surprisingly, however, the BI based crossdating results for LAE are the strongest of all four living

247 sites with a T-value of 13.2. These observations for LAE clearly show the “purer” climatically dominated
248 common signal expressed in BI compared to RW which can be strongly affected by non-climatic factors.

249 It is important to highlight that the T-value results for both RW and BI against the SMM are only
250 marginally weaker than for the “optimal” regional reference record. This is an encouraging observation as it
251 suggests that initial dating of a historical site could be performed using the full SMM data-set. Once dated,
252 provenancing the historical material could then be performed using the regional reference data-sets or
253 even individual sites.

254 As with the living “analogue” sites (Figure 2), BI based T-values for the six historical sites are
255 generally stronger compared to RW, but overall the results are weaker (Figure 3). This observation is partly
256 related to the relatively low number of dated TR series included in some of the historical site chronologies
257 (e.g. only two timbers for Red House and Belladrum, Table 2). However, the fact that a significant crossdate
258 can be identified using such a low number of timbers is encouraging (but see later discussion). The low T-
259 values when using RW (Figure 3) clearly show why it has been so difficult to date historical structures in
260 Scotland using this TR variable alone. The utilisation of BI has greatly improved our chances of dating
261 historical pine samples.

262 Compared to living “analogue” sites (Figure 2), the provenancing results for the historical samples
263 are more ambiguous (Figure 3). Often, the highest T-values using RW and BI identify different timber source
264 regions. For example, for Inverey Byre, RW suggest SC, while BI suggests CNT. We are fairly confident that
265 the Inverey Byre timbers would have been locally sourced and therefore should crossdate more strongly
266 with the SC region (highlighted in Figure 3). Similar ambiguities with respect to potential timber provenance
267 are noted for all the historical sites except Badden Cottage which appears to be most closely related to the
268 NC region. These ambiguous provenancing results do not influence the overall conclusion that BI is a
269 superior TR variable for dating historical conifer material but they do indicate that site/phase chronology
270 replication is an important factor that must be taken into account when crossdating.

271

272 **3.3 Crossdating and site replication**

273 Figure 4 presents the mean correlation (± 2 standard deviations) between the increasingly
274 replicated sub-sampled site chronologies (1 through to 20 trees) and the mean of the rest of the data in the
275 SMM data-set. As would be expected (see Wigley et al. 1984) the mean correlation is lower for
276 chronologies derived from only a single tree and becomes higher as replication increases. On average, the
277 mean correlation for a site chronology of only a single tree is 0.35 and 0.48 for RW and BI respectively. For
278 10 trees, these values increase to 0.76 and 0.86. So again, the correlation results are higher for BI than RW
279 as was noted from the crossdating T-value results (Figures 2 and 3).

280 These mean correlation values, however, only tell half the story. As with any sub-sampling exercise,
281 the range in values is crucial to understand the noise and variability in the data. It is not surprising that for
282 sites replicated with only one tree, the 2-sigma standard deviation range of correlation values is rather
283 large – essentially from 0 to 1 for BI. As replication increases, this 2-sigma range decreases. Crucially, this
284 large range in potential correlation values, when replication is low, highlights the potential danger of both
285 type I and II dating errors and caution is advised when dating using only single series. This is also relevant
286 when attempting to date single sub-fossil samples (Wilson et al. 2012). Of course, identifying the same
287 calendar date using both RW and BI provides added confidence that the identified date is more likely to be
288 correct. The horizontal dotted lines in Figure 4 denote the correlation needed ($r = 0.41$) to attain a T-value
289 of 4.0 when the period of overlap is 80 years. As the 2-sigma error range decreases with increasing
290 replication, we can use this variability range to predict that a “correct” date can be identified 95% of the
291 time when site/phase chronology replication is ca. 5 and ca. 4 trees when using RW and BI respectively.

292 In many respects, the subsampling exercise of the SMM data-set (Figure 4) is an idealised exercise
293 as the results likely will only be relevant for historical sites built using timbers that grew originally in the
294 areas represented by the SMM data. However, the exercise does provide a guide to identify an ideal
295 minimum number of samples needed to date a historical phase chronology within the Scottish Highlands.
296 To test the applicability of this modelling exercise, the correlation values for the living “analogue” and

297 historical sites used to generate the T-values in Figures 2 and 3 are also plotted on Figure 4. Although the
298 results are better for BI than RW, the actual correlation values for many of the sites are outside the 2-sigma
299 variability range of the sub-sampling results. Using BI, the four living analogue site correlations do sit within
300 the modelling range, but for RW, LAE and RYV are weaker than expected. Although the LAE results could be
301 explained by disturbance influences on this site's growth (Rydval et al. 2016a), this explanation is likely not
302 relevant for RYV. The results are less robust for the historical sites. Only Red House and Belladrum sit within
303 the modelled range using RW. The other four sites are much weaker and a T-value of 4.0 could not be
304 attained against the SMM. Results are marginally better using BI for Inverey Byre, Granton-on-Spey and
305 Badden Cottage but are still weaker than expected.

306 To explore these poorer than expected results, we examine the coherence between the historical
307 site chronologies and the SMM reference chronology in more detail (Figure 5). Specifically, sliding 31-year
308 window correlations are shown between the historical and SMM chronologies for both TR variables. As
309 expected, the BI based correlations are higher than RW. However, for all six sites, the coherence between
310 the site and regional chronologies is not time-stable and in general terms, when replication is low, between
311 series correlation is also low. This is hardly surprising (see Figure 4), but it does appear that when
312 calculating the correlation (and associated T-value) using the full period of overlap, the values can be
313 detrimentally impacted due to poorly replicated periods. To partly overcome this, the mean of the sliding
314 correlations could be used rather than the correlation calculated over the full overlap period. This reduces
315 the overall influence of the low replicated periods. The difference between the correlation values for the
316 full period and the mean of the sliding correlations (Figure 5 - top right corner of each panel) can be
317 substantial. For example, the full period RW (BI) based correlation for Inverey Byre is 0.31 (0.60), but
318 increases, using the sliding correlations, to 0.55 (0.75). In fact, the mean of the sliding correlations is almost
319 always higher than the full period correlation except for Belladrum where there is a slight decrease for RW.

320 As well as deriving a mean correlation using 31-year sliding windows, mean tree replication
321 (derived from the replication histograms in Figure 5) can also be calculated via the sliding window
322 approach. In the case of Inverey Byre, for example, although the historical site includes 10 timbers, the
323 mean replication of the sliding 31-year windows is 7.97. Using these new estimates for r and n , the site
324 based correlation results shown in Figure 4 are updated and presented along with the same modelling
325 results in Figure 6. Focussing on BI, the living "analogue" and historic site results now sit well within the
326 modelled 2-sigma range. The results for RW, although improved, still however identify some sites (LAE,
327 Badden Cottage, MacRobert House, Inverey Byre and Granton-on-Spey) outside the 2-sigma variability
328 range. As discussed earlier, the LAE RW results can be explained by human disturbance (see also Rydval et
329 al. 2016a). Explaining the poor RW based results for the other historical sites is more of a challenge as we
330 do not know the original growth location of the timbers. The sliding correlations (Figure 5) clearly show
331 more time stable coherence between the site chronologies and the SMM for BI data. The RW data for
332 almost all the sites express periods with significant weak coherence which may well be related to some
333 form of disturbance (Rydval et al. 2016a) obscuring the climatic influence on tree growth. This is a difficult
334 hypothesis to test without specifically focussing on living sites only (i.e. LAE), but one clear conclusion from
335 this work is that BI appears to be less sensitive to such issues and shows great potential as an important
336 new TR variable for crossdating conifer material (see also discussion in Rydval et al. in review-b).

337

338 **3.4 The wider geographical potential of BI based dating**

339 The discussion so far has focussed specifically on the ability of using BI to improve the likelihood of
340 identifying a correct crossdate of historic conifer wood samples in Scotland. We believe, however, that BI
341 has the potential to improve the dating of imported conifer material where the original provenance is
342 unknown. Scotland has a long history of timber importation for construction (Crone and Mills 2012). This
343 adds a substantial challenge for dendrohistorical dating as a network of relevant reference chronologies
344 from across Europe is needed for the locations where the timbers originated. It is also likely that
345 construction timbers may reflect different species. For conifer species, however, we hypothesise that the
346 use of BI may minimise the need for the development of specific local/species reference chronologies

347 because, at least for locations where temperature is the dominant control on tree growth, BI (and MXD)
348 almost always reflects late growing season temperatures. Therefore, BI or MXD chronologies from different
349 conifer species may correlate significantly with each other as their variability represents the same general
350 response to late summer temperatures. Also, as temperature is spatially more homogenous than
351 precipitation, crossdating using temperature sensitive BI or MXD chronologies could theoretically be
352 possible over quite large regions. The number of long (> 500 years) BI/MXD records is continually increasing
353 as a result of dendroclimatic studies (Wilson et al. 2016), and although the Northern Hemispheric TR
354 network is still sparse in places, these data should help facilitate the dating and provenancing of historical
355 material, especially within Europe.

356 To explore this hypothesis, we compare the spatial climate response of the SMM record (RW and
357 BI) with TR records from Jämtland (central Sweden (RW and MXD from Scots pine) – Zhang et al. 2015),
358 Rogen (central Sweden (RW and BI from Scots pine) - Fuentes et al *in prep*), Miseri (Austria (RW and BI from
359 Cembran pine) – Nicolussi et al. 2015), Lötschental (Switzerland (RW and MXD from European larch) –
360 Büntgen et al. 2005, 2006) and the Pyrenees (RW and MXD from Mountain pine – Büntgen et al. in review).
361 The spatial correlation for each of these site/regional chronologies for BI/MXD and RW against mean July-
362 August (May-September for PYR) gridded mean temperatures across Europe (Harris et al. 2014) allow an
363 assessment of the potential spatial extent over which these data could be used for the dating of historical
364 material (Figure 7). The stronger climate signal expressed by BI/MXD compared to RW is evident with an
365 expected weakening of the temperature signal at lower latitudes (Babst et al. 2012). Importantly, the
366 spatial domain expressed by the strong BI/MXD correlations is much greater than RW suggesting that these
367 BI and MXD data-sets could be used as historical reference chronologies over relatively large regions (ca.
368 300-500km around each reference chronology) – meaning that the current relatively sparse network of
369 long BI/MXD chronologies may suffice to facilitate crossdating over most parts of Europe.

370

371 4. Conclusion

372 Using a Scottish case study, this paper has shown that the utilisation of BI can substantially increase
373 the probability of attaining a successful crossdate of conifer samples taken from historical structures. Site
374 specific factors influencing growth can potentially weaken the climatic signal expressed in RW while BI
375 appears more resilient to such effects and retains a “purer” common climate related signal even from sites
376 affected by disturbance. RW data should however not be ignored. From our experience of dating sub-fossil
377 material using both RW and BI (Wilson et al. 2012; Rydval et al. in review-a), more confidence in a crossdate
378 can be attained for a sample when the same calendar date is independently indicated by both TR variables.
379 The quality of BI data can be detrimentally affected by discolouration, rot, wormholes and reaction wood
380 which weaken the signal and so the RW based validated crossdate can often be important if T-values using
381 BI are low.

382 A general guide for crossdating in Scotland is that so long as pine timbers are sourced locally (or
383 within the region represented by the SMM), dating should be guaranteed, when using BI, so long as a
384 site/phase master is replicated with at least 4 trees (with a mean sample length of 80 years) although
385 varying replication through time may have a significant impact on dating success and caution is advised
386 when including poorly replicated sections of chronologies. Samples of greater length, as well as measuring
387 2 or more radii from the same sample, will of course increase the probability of crossdating success.
388 Crossdating is undoubtedly possible with RW data, but as such data express a weaker regional scale climate
389 signal and can be influenced by site specific effects, the probability of acquiring a correct date will be
390 reduced without also concurrently using BI.

391 Finally, it is important to emphasise that the Scottish pine network was sampled for dendroclimatic
392 purposes (Wilson et al. 2012; Rydval et al. 2016b, in review-a) using trees from sites located at higher
393 elevations (300-600 m a.s.l.) where temperature is the predominant limiting factor controlling growth. It is
394 basic dendroecological theory that the response of trees to climate will vary with elevation (Fritts et al.
395 1965; LaMarche 1974; Kienast et al. 1987; Wilson and Hopfmüller 2001) so low and high elevation
396 chronologies of the same species may not necessarily correlate (Wilson et al. 2004). This is not a problem in

397 itself, but reference chronologies must be developed for regions (and species) relevant to the source
398 regions of construction timbers. The large spatial finger-print of the temperature signal expressed by BI
399 (and MXD) data across Europe (Figure 7) suggests that a sparse network of temperature sensitive BI/MXD
400 chronologies could suffice for dating and possibly provenancing historical material from across this large
401 continental region. However, no analysis of the climate signal expressed in BI/MXD data from lower
402 elevation conifer sites has been performed. Therefore, for historic structures built with conifer timbers
403 from lower elevations, substantial effort is needed to create lower elevation BI/MXD reference
404 chronologies not only to test their spatial coherence but also to assess their dating (and climatic) potential.
405

406 **Acknowledgments**

407 The Scottish pine network expansion has been an ongoing task since 2006 and funding must be
408 acknowledged to the following projects: EU project 'Millennium' (017008-2), Leverhulme Trust project
409 'RELiC: Reconstructing 8000 years of Environmental and Landscape change in the Cairngorms (F/00
410 268/BG)', the Native Oak and Pine project or 'NOAP' (Historic Scotland) and the NERC project 'SCOT2K:
411 Reconstructing 2000 years of Scottish climate from tree rings (NE/K003097/1)'. Further PhD funding for
412 Milos Rydval is acknowledged from The Carnegie Trust.

Table 1: Analogue historical sites using independent living data from the Scottish Pine network. MSL = mean sample length. RBAR = mean inter-series correlation of 1st differenced detrended data; N (EPS 0.85) = number of trees needed to attain an EPS of 0.85.

Site Name	Figure 1 code	Date	MSL	no. of dated series	no. of trees	No. of undated series and comment	RW RBAR	N (EPS 0.85)	BI RBAR	N (EPS 0.85)
Inverey Byre	A	1668-1791	85.0	10	10	1. short sequence	0.40	8.5	0.41	8.1
MacRobert House	B	1724-1848	93.0	7	7	13. Fragmented, broken and short series	0.25	17.0	0.32	12.2
Red House	C	1707-1808	89.3	2	2	14. Fragmented, broken and short series	0.29	13.7	0.32	11.9
Belladrum	D	1742-1861	97.8	4	2	zero	0.40	8.5	0.46	6.7

Figure 1: Location map showing the individual locations of all 44 pine sites in Scotland, the regions represented by the five pine region reference series (including individual TR series replication for each parameter), the four living “analogue” test sites and the six historical structures.

Figure 2: T value crossdating results against regional and SMM reference chronologies. RW in red and BI in blue. Grey shading denotes the region within which each site is located. Loch Coldair is located in the so called “network hole” so no shading is shown but geographically it is more closely located to NC.

Figure 4: Modelled change in correlation as sample replication (N) increases. The black line mean correlation and 2-sigma envelopes (red = RW; blue = BI) denotes bootstrap sampling (1000 times) of the SMM of sample replication with 1 to 20 trees using two 80-year periods (1720-1800 and 1820-1900). The full period correlation values used to generate T-values in Figures 2 and 3 are also plotted against the number of timbers for the four test and six historical sites.

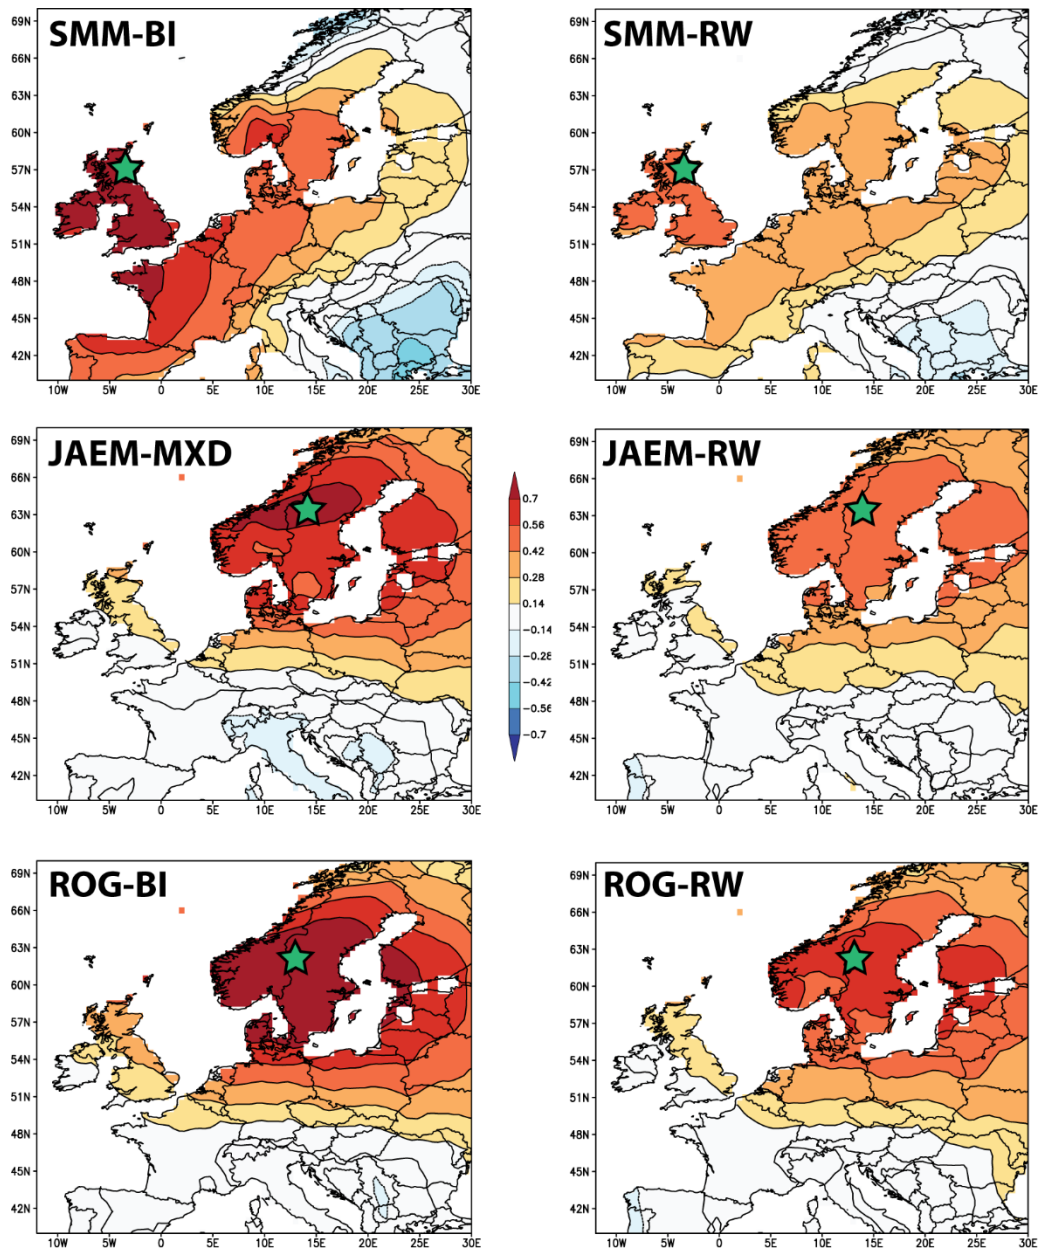

660
 661

662 **Figure 5:** Sliding 31-year correlation values between each historical site chronology and the SMM master
 663 chronologies for both RW (red) and BI (blue). Grey histograms denote TR series replication for each
 664 historical site, while the black line shows individual tree replication. “Full period r” = the correlation value
 665 generated between the historical chronology and SMM used to produce the T-values in Figure 3. “Mean
 666 sliding r” = the mean correlation from the sliding 31-year correlations.

667
 668
 669
 670

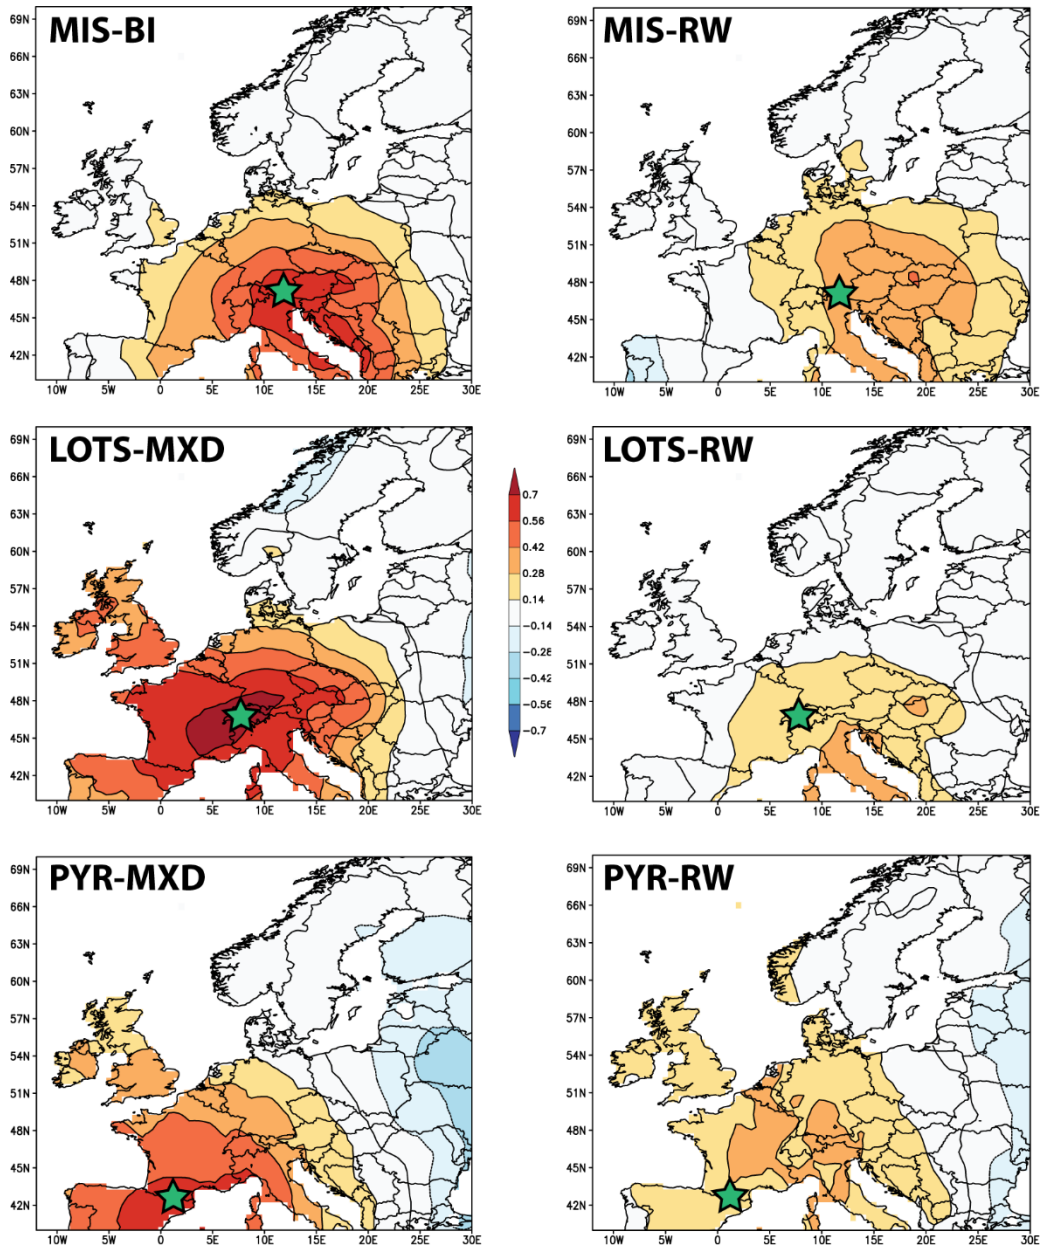

Figure 6: as Figure 4 but using mean of sliding correlation and mean n through time.

671
672

673 **Figure 7a:** Spatial correlation (1902-2004) between site/regional BI/MXD and RW chronologies from
 674 Scotland (SMM – this paper), central Sweden (Jämtland – JAEM (Zhang et al. 2015); Rogen – ROG (Fuentes
 675 et al *in prep*)), Austria (Miseri – MIS (Nicolussi et al. 2015)), Switzerland (Lötschental – LOTS (Büntgen et al.
 676 2005, 2006)) and the Pyrenees (PYR – Büntgen et al. in review) and CRU TS3.23 (Harris et al. 2014) 0.5-
 677 degree gridded mean July-August temperatures (May-September for PYR). The BI data have been inverted
 678 to provide the same positive correlation with temperature as expressed by the MXD data. All data were 1st
