## Abstract

Researchers and engineers have widely adopted the discrete element method (DEM) for simulation of bulk materials. One important aspect in such simulations is the determination of suitable material and contact law parameters. Very often, these parameters have to be calibrated because they are difficult to measure or, like rolling friction, do not have a physical analogue. Moreover, coarse-grained particle models are commonly used to reduce computational cost and these always require calibration. Despite its disadvantages, trial and error remains the usual way to calibrate such parameters. The main aim of this work is to describe and demonstrate a methodical calibration approach which is based on Latin hypercube sampling and Kriging. The angle of repose and bulk density are calibrated for spherical glass beads. One unique feature of this method is the inclusion of the simulation time-step in the calibration procedure to obtain computationally efficient parameter sets. The results show precise calibration outcomes and demonstrate the existence of a solution space within which different parameter combinations lead to similar results. Kriging meta-models showed excellent correlation with the underlying DEM model responses. No correlation was found between static and rolling friction coefficients, although this has sometimes been assumed in published research. Incorporating the Rayleigh time-step in the calibration method yielded significantly increased time-step sizes while retaining the quality of the calibration outcome. The results indicate that at least particle density, Young's modulus and both rolling and static friction coefficients should be used for calibration; trial-and-error would be highly inefficient for this number of parameters which highlights the need for systematic and automatized calibration methods.

## 1. Introduction

Although the discrete element method (DEM) was developed in the 1970s [1], it is only recently that researchers and engineers have been able to run DEM simulations of sufficiently large size and complexity

---

\*Corresponding author: rackl@fml.mw.tum.de

1 to be practically useful. This has caused a rapid growth in the adoption of DEM [2], enabled by continual  
2 advances in affordable computational power. Huge numbers of studies have shown the usefulness of DEM  
3 for modelling the behavior of bulk solids in industrially relevant systems such as fluidised beds, silos, mixers  
4 or mills.

5 One major benefit of DEM is that the simulations require specification of a relatively small number of  
6 microstructural parameters. However, it can be difficult to establish suitable values for all of these model  
7 inputs. For example, input parameters cannot be obtained by laboratory testing for coarse-grained simula-  
8 tions in which the particle diameters are increased beyond their physical values to reduce the computational  
9 requirements of a simulation, e.g., [3–5]. Even if particle diameters are simulated accurately, other pa-  
10 rameters can be difficult to relate to physical measurements, e.g., numerical damping coefficients [6] or  
11 rheological parameters required in the force–displacement laws [7]. The interparticle friction coefficient is  
12 often increased to unphysically large values in an attempt to capture particle irregularity [8]. Additional  
13 parameters which lack a physical basis are usually needed when grain crushing [9] or rolling resistance [10]  
14 are considered in the model.

15 When the foregoing limitations of laboratory experiments to supply model input parameters are con-  
16 sidered, it is unsurprising that most DEM simulations contain parameters which can be obtained only  
17 by calibration. Calibration involves varying the unknown parameters until a satisfactory match has been  
18 achieved between the simulation results and the corresponding physical measurements for the response(s) of  
19 interest. Calibration is often done in an inefficient manner based on trial and error. Trial-and-error calibra-  
20 tion has many obvious disadvantages [7]: it is not known in advance how many simulations will be needed  
21 for calibration; the success of the method depends on the modeller’s experience; little, if any, mechanistic  
22 insight is gained; the calibrated parameters may be suboptimal; and using a trial-and-error approach rapidly  
23 becomes impractical as the number of parameters increases. Furthermore, DEM simulations can be very  
24 computationally expensive so running more simulations than essential for calibration is undesirable.

25 The significant disadvantages associated with trial-and-error calibration of DEM input parameters have  
26 motivated research into alternative approaches based on design of experiments (DoE) methods. Yoon [11]  
27 uses response surface analysis and a Plackett–Burman experimental design to identify suitable parameters  
28 to simulate uniaxial compression of bonded rock. Favier et al [12] and Johnstone [13] both use DoE methods  
29 to calibrate DEM models based on experimental measurements. Benvenuti et al. [14] train an artificial  
30 neural network for DEM simulation parameter identification. However, none of these calibration approaches  
31 are widely used in industry where *ad hoc* trial-and-error methods remain predominant.

32 In this paper, a novel calibration procedure is described which is based on Latin hypercube sampling and  
33 Kriging [15]. This workflow was designed to be automated, i.e., to run efficiently with minimal user inter-  
34 vention. It was implemented using purely open-source software including LIGGGHTS [16] and GNU Octave  
35 [17]. Both the open-source implementation and the high level of automation are intended to encourage the

1 widespread adoption of this calibration method. Another novel aspect is the inclusion of the simulation time-  
2 step in the calibration process. In most cases, DEM adopts an explicit, conditionally-stable time-stepping  
3 algorithm. The size of the largest time-step which maintains numerical stability is strongly dependent on the  
4 particle density and stiffness. Considering the simulation time-step during calibration means that optima  
5 requiring small time-steps to maintain stability are disfavoured. This ensures that the calibration process is  
6 prevented from converging to a solution which causes the simulation to run prohibitively slowly.

7 The main aim of this paper is to describe and demonstrate a novel calibration method. Spherical glass  
8 beads are used as the bulk material. Two responses are calibrated, angle of repose and bulk density, while  
9 simulation time-step is also considered during calibration. Subsidiary aims are as follows: (i) to demonstrate  
10 that significantly larger time-steps can be achieved by explicitly including the time-step as a factor in the  
11 calibration process, while still achieving an excellent match between the experimental data and the model; (ii)  
12 to show that parameter sets which differ substantially can yield similar outcomes; (iii) to explore interactions  
13 among the DEM input parameters being calibrated.

14 This calibration approach is generally applicable to all types of DEM simulation. The example presented  
15 in this paper is for a conventional DEM simulation in which each simulated particle represents one physical  
16 particle. However, the method has even greater potential for coarse-grained simulations for which the number  
17 of parameters requiring calibration can be very large.

## 18 **2. Materials and Methods**

19 This section contains a brief overview of DEM, followed by a more detailed description of the specific model  
20 considered in this study.

### 21 *2.1. Discrete Element Method*

22 Both hard-sphere and soft-sphere DEM simulations are possible; the latter are more frequently used and are  
23 the focus of this paper. The particle geometry is idealized to reduce the computational requirements: often  
24 spheres are used in three-dimensional simulations. The density and stiffness of each particle can differ. The  
25 particles are not permitted to deform during the simulation; instead deformation is captured by allowing  
26 the particles to overlap at contacts with surrounding particles and boundary walls. DEM is driven by  
27 a time-stepping algorithm, often a central difference, velocity–Verlet scheme. During each time-step [18],  
28 interparticle forces are evaluated at contact points based on a defined force–displacement law. This contact  
29 model is almost always based on either a linear, Hookean spring or a nonlinear, Hertzian spring along  
30 the contact normal. The interparticle contact forces are summed, along with body forces such as gravity,  
31 to calculate resultant forces for each particle. Then Newton’s Second Law is applied to determine the  
32 translational and angular particle accelerations which are numerically integrated to find particle velocities

1 and displacements. These displacements are used to update the particle positions at the end of each time-  
 2 step. Individually, these calculations are very straightforward. However, as millions of particles may be  
 3 simulated using time-steps of the order of nanoseconds, the computational effort can be very considerable  
 4 to simulate a short time period.

## 5 *2.2. Investigated DEM Model of this Study*

6 All simulations were run using the public version of the LIGGGHTS [16] DEM code. A Hertz–Mindlin  
 7 contact model was chosen for these simulations along with an elastic–plastic spring–dashpot (EPSD) rolling  
 8 friction model. This model incorporates viscous damping in its formulation [19]. The critical time-step for  
 9 each simulation was computed using Equation 1 where  $G$  is the shear modulus,  $\rho$  is particle density,  $\nu$  is  
 10 Poisson’s ratio and  $r$  is the radius of the smallest particle.

$$dt_r = \frac{\pi r \sqrt{\frac{\rho}{G}}}{0.1631\nu + 0.8766} \quad (1)$$

11 The time-step used for the DEM simulations was taken as a quarter of this critical Rayleigh time-step.  
 12 For this paper, it is assumed that the time-step is solely a function of the parameters used in Equation 1.  
 13 Although it is known that the simulation time-step must be reduced to ensure stability when particle  
 14 relative velocities are large, the nature of this reduction is currently unquantified. In cases where the  
 15 relative velocities are large, it is noted that the factor by which Equation 1 is multiplied (0.25) may need to  
 16 be reduced to maintain stability.

17 The effect of this time-step on the calibration was controlled by means of a weighting factor. This  
 18 weighting factor, WRL, was one of the seven factors adjusted in the calibration process. Apart from the  
 19 Rayleigh time-step, two responses were calibrated: bulk density and angle of repose. The system shown  
 20 schematically in Figure 1 was simulated to obtain these responses. It consists of a horizontal steel plate with  
 21 a steel cylinder of diameter 100 mm resting on top so that the plate obstructs the bottom of the cylinder. A  
 22 rigid ring of height 3 mm and diameter 100 mm is affixed to the steel plate to prevent particles from rolling  
 23 away on the flat surface. Each simulation is run in the following manner. Particles of diameter 5 mm are  
 24 poured into the cylinder under gravity ( $g = 9.81 \text{ m s}^{-2}$ ) to a height exceeding 50 mm and the system is  
 25 allowed to settle. Any particles above 50 mm are subsequently removed from the simulation domain and  
 26 the system is given time to settle again. The poured bulk density is found using the total particle mass and  
 27 fill height. Then the cylinder is raised at a constant speed of  $10 \text{ mm s}^{-1}$  so that a heap is formed under the  
 28 influence of gravity. After the system has settled, monochrome screenshots of the top-down perspective and  
 29 side view are created. The angle of repose of the heap is found using the verified image processing algorithm  
 30 described in Appendix A. The bulk density and angle of repose are compared with literature values for glass

1 beads:  $1500 \text{ kg m}^{-3}$  and  $22^\circ$ , respectively ([20, p.16], [21]). Table 1 shows the values of the model input  
 2 parameters which were fixed for all simulations.

3 Seven parameters were used in the calibration process: the particle density, the Young’s modulus, the  
 4 static friction coefficients and rolling friction coefficients between two particles and between particles and  
 5 walls, and the weighting factor controlling the effect of Rayleigh time-step on the calibration (WRL). There  
 6 are an infinite number of parameter sets which would satisfy the requirements for bulk density and angle  
 7 of repose. By considering Rayleigh time-step, the single parameter set which maximised the time-step,  
 8 and hence the efficiency of the simulation, was favored. Although particle density is often easily measured,  
 9 non-physical values may be used in quasi-static simulations to increase the size of the critical time-step: so-  
 10 called ‘density scaling’. Furthermore, for coarse-grained simulations, the density required for the simulated  
 11 particles inevitably differs from that of the physical particles so particle density usually requires calibration  
 12 for coarse-grained simulations. The experimental plan which describes exactly how these parameters were  
 13 varied is discussed in subsection 2.3.4.

### 14 2.3. Calibration Process

15 The calibration process described in this paper includes sampling the model to be calibrated at randomly,  
 16 yet evenly, distributed points and adopting Kriging as a meta-model technique.

#### 17 2.3.1. Latin Hypercube Sampling

18 Latin hypercube sampling was first described by McKay et al. [22]. The idea is to randomly, yet evenly,  
 19 distribute samples in an  $N$ -dimensional factor domain.

20 Let  $V_k \in [v_{k,L}; v_{k,U}]$  (where  $v_{k,L} < v_{k,U}$  and  $v_{k,L}, v_{k,U} \in \mathbb{R}$ ) be the  $k^{\text{th}}$  interval of interest of a number  
 21 of factors  $N \in \mathbb{N}^+$  in which  $n \in \mathbb{N}^+$  sample locations are to be distributed. First of all, the domain for  
 22 each  $V_k$  needs to be split into  $n$  evenly-spaced, non-overlapping subdomains  $W_{k,i}$ . The width  $w_k$  for each  
 23  $V_k$ ’s subdomain can be determined from Equation 2 and the interval of the  $i^{\text{th}}$  subdomain  $W_{k,i}$  is given by  
 24 Equation 3.

$$w_k = \frac{v_{k,U} - v_{k,L}}{n} \quad (2)$$

$$W_{k,i} = \begin{cases} [(i-1)w_k + v_{k,L}; iw_k + v_{k,L}], & i \in [1; n-1] \\ [(n-1)w_k + v_{k,L}; v_{k,U}], & i = n \end{cases} \quad (3)$$

25 A random value  $x_{k,i}$  is drawn from each of the subdomains  $W_{k,i}$ . A random set is selected from the  
 26 permutation of all  $x_{k,i}$  such that each  $W_{k,i}$  occurs once. This leads to  $n$  tuples which form an  $N$ -dimensional  
 27 Latin (hyper) cube, where each tuple element is unique and the tuples are well-distributed.

1 In order to ensure an evenly-distributed set of tuples, the Octave package *stk* [23] created 5,000 Latin  
 2 hypercube designs per included calibration factor, following the process described above. Subsequently,  
 3 the distance  $d_c$  between each tuple in a respective design was computed according to the Euclidean norm  
 4 (Equation 4). In Equation 4,  $p$  and  $q$  are tuples and  $p_j, q_j$  the  $j^{\text{th}}$  tuple. The distance  $d_c$  was computed for  
 5 all  $h$  tuple combinations per design.

$$d_c(p, q) = \sqrt{\sum_{j=1}^h (p_j - q_j)^2} \quad (4)$$

6  $d_c$  was used as a criterion to select the design where the minimum distance of all tuple combinations was  
 7 the largest. Thus, the design selected for the sample set was the one whose minimum distance  $d_{\text{sel}}$  satisfied  
 8 Equation 5 for all designs. This is called the ‘MAXIMIN’ criterion in the literature, e. g., [24, p.183 ff.].

$$\min(d_{\text{sel}}) = \max(\min(d_c)) \quad (5)$$

### 9 2.3.2. Kriging

10 Kriging is a general term for a collection of statistical regression methods. There exist different modifications  
 11 [25, p. 154], some of which are not clearly defined. The Kriging method used for this work is *Universal*  
 12 *Kriging* or *Kriging with drift*. As with every regression method, the main aim is to predict values at  
 13 unsampled locations from a given set of sample locations and corresponding sample response data.

14 The theoretical background described in this section is given in standard statistics references, e. g., [25,  
 15 p. 195 ff.]. In Universal Kriging, the responses  $Z_s(x_s)$  at a number,  $N$ , of sample locations  $x_s$  are considered  
 16 to consist of a deterministic part  $S(x_s)$  and a random part  $R(x_s)$ . Within the scope of this study,  $S(x_s)$  in  
 17 Equation 6 represents a first-order polynomial function with  $K$  coefficients  $\beta_i$ , which are initially not known,  
 18 as well as the functions  $f_i$ . Hence, Equation 6 can be rewritten as Equation 7.

$$Z_s(x_s) = S(x_s) + R(x_s) \quad (6)$$

$$Z_s(x_s) = \sum_{i=1}^K \beta_i f_i(x_s) + R(x_s) \quad (7)$$

19 Equation 7 can be expressed for the response data of interest  $\mathbf{Z}_u$  as in Equation 8.  $\mathbf{Z}_u$  depends on the  
 20 unsampled locations of interest  $\mathbf{x}_u$ , the design matrix  $\mathbf{D}_{\text{lhs}}$  as obtained from Latin hypercube sampling and  
 21 a vector of coefficients  $\boldsymbol{\beta}$ . Using an anisotropic Matérn covariance matrix [26, p. 12-14], the coefficients  
 22 and weights for  $\boldsymbol{\beta}$  and  $R(\mathbf{x}_u)$  are computed by means of the restricted maximum likelihood method (ReML,  
 23 [26, p. 170])). Note that the *stk* package in Octave allows for estimation of (measurement) noise from the  
 24 response data, which was done for this study. By including this information, the Kriging surrogate models  
 25 implicitly change their property from interpolation to approximation [27, p. 156].

$$\mathbf{Z}_u(\mathbf{x}_u) = \mathbf{D}_{\text{lhs}}\boldsymbol{\beta} + R(\mathbf{x}_u) \quad (8)$$

### 2.3.3. Calibration Approach

The general calibration approach followed by a human calibrator is as follows. Initially, DEM models have to be created which represent physical measurement setups. These models are needed to generate the desired response(s). In the next step, the material and contact law parameters to be used for calibration are selected. Typically, the calibrator wishes to minimize the number of calibration parameters, since each additional parameter increases the complexity of the calibration task. After this, material parameters with which to start the calibration are either measured or taken from literature. Very often, only parameter ranges are available, as there is always some form of variation in the measurement data. Once the parameters have been chosen and set, the DEM models are sampled using different parameter sets to gain insight into which parameter or combination of parameters influences the responses. As soon as the relationship between calibration parameters and response values has been established, the values of the calibration parameters are adjusted until the responses match the experimental values within a desired tolerance, e.g., standard error of the measurement. It is obvious that the sampling process as well as parameter adaptation are highly repetitive tasks which involve a lot of data handling. Thus, these steps were chosen to be automatized. Using Latin hypercube sampling and Kriging, the main aim was to develop a versatile and robust calibration process.

In order to convert the widely-used trial-and-error approach for DEM material parameter calibration into a method suitable for automatization, three presumptions were made. (i) If no parameter value is available or it varies with different bulk solid batches, the person calibrating will be likely to find this parameter to lie within an interval, rather than being a constant value. This is often the case for friction values, which are influenced by many micromechanical factors, for example. Furthermore, when physical measurements are unavailable or difficult to obtain, the calibrator will find a range of values in the literature. Uncertainty in the order of magnitude of a parameter can be reflected by increasing the interval width. Nonetheless, increasing it for the particle density or Young's modulus has to be done carefully since both also influence the Rayleigh time-step. Excessively wide intervals for either of these parameters could impose excessive weight on the Rayleigh time-step during the calibration [28]. (ii) Incorporating more experimental data for the calibration will increase the validity of the calibrated DEM parameter set. The calibration procedure is therefore designed to work with several DEM models and responses simultaneously. (iii) A human calibrator is incapable of efficiently capturing effects of a single factor and the interactions at the same time, particularly if there are several responses. However, this is the most important prerequisite when working with multivariate data and the key to reducing the number of calibration runs to a minimum. As a consequence, the task of keeping track of effects and predicting the results of parameter changes is carried

1 out by means of a meta-model (Kriging) in combination with suitable sampling (Latin hypercube) as well  
2 as numerical optimization.

3 Figure 2 outlines the workflow of the three phases of the calibration process. After the calibration  
4 parameters and their respective intervals are set by the user, the process requires no further user intervention.  
5 It starts by generating a set of sample parameter sets based on Latin hypercube sampling, forwards them to  
6 the DEM models and collects the response data (sampling phase). In the next step, the Kriging meta-models  
7 are parameterized with the sample parameter sets and corresponding responses. Using these meta-models,  
8 an optimization process is initiated (1<sup>st</sup> optimization phase). The starting value of the optimization is the  
9 mean value of each parameter interval. The idea is to use the computationally cheap meta-models to identify  
10 a promising starting value for the DEM optimization step which is far more computationally expensive.  
11 Finally, the optimal parameter set from the meta-models is used as starting value for the optimization with  
12 the actual DEM models (2<sup>nd</sup> optimization phase). This is to verify the prediction from Kriging and refine  
13 the quantitative calibration outcome.

14 For a conventional DEM simulation without coarse graining, it is possible that the number of parameters  
15 requiring calibration may be very small. For cases with only one or two unknown parameter values, the  
16 development of Kriging meta-models is unnecessarily expensive. This calibration method requires a larger  
17 set of unknown parameters in order to be viable.

18 Optimization was carried out using the multi-objective Levenberg-Marquardt residual minimization al-  
19 gorithm [29, 30], as implemented in the GNU Octave package *optim* [31]. The optimization was set to  
20 terminate when the improvement in the objective function was less than 2% between two iterations. The  
21 reason for this was to avoid a large number of optimization steps, of which the last ones would only improve  
22 the absolute calibration outcome marginally. The maximum absolute tolerance between the desired values  
23 and the calibrated responses should be specified by the calibrator; because bulk solid measurements can  
24 feature scatter of several percent, it would be unnecessary and wasteful to calibrate the model parameters  
25 meticulously.

26 The same multi-objective cost functions are used for both optimization steps. Response values are taken  
27 into account using Equation 9, where  $s_i$  is the DEM response and  $m_i$  ( $> 0$ ) is the corresponding desired  
28 experimental value.

$$c_i = \frac{s_i - m_i}{m_i} \quad (9)$$

29 With regard to computational efficiency of the calibrated DEM parameter set, a large value of the  
30 Rayleigh time-step size is desired. However, unlike angle of repose or bulk density, there exists no globally  
31 optimal Rayleigh time-step size since Equation 1 is unrestricted in its maximum value. The cost function  
32 used in this study hence seeks to obtain the largest possible value with regard to the initially specified  
33 parameter intervals. It is shown in Equation 10, where  $r_{max}$  and  $r_{min}$  are the maximum and minimum

1 possible Rayleigh time-steps, respectively,  $dt_r$  is the Rayleigh time-step of the current parameter set and  
 2  $WRL$  is a weighting factor, subject to investigation in this study. The authors are unaware of any prior  
 3 studies where the Rayleigh time-step size was actively considered as a calibration target.

$$t_i = WRL \cdot \frac{r_{max} - dt_r}{r_{max} - r_{min}} \quad (10)$$

4 The approach described above is generally applicable. The specific example used to demonstrate its  
 5 usefulness contains seven unknown parameter values as described in subsection 2.2. The experimental plan  
 6 for this specific case is given in subsection 2.3.4 and the results are presented and discussed in section 3.

#### 7 *2.3.4. Experimental Plan for Numerical Experiments*

8 The experimental plan of this study is listed in Table B-1 in the appendix. It was created using the Design  
 9 of Experiments (DoE) package RcmdrPlugin.DoE [32], of the statistical programming software R [33]. The  
 10 Design of Experiments comprises four factors on two levels and two factors on three levels and is based on  
 11 an orthogonal array (L72.2.56.3.2 in RcmdrPlugin.DoE ), which was optimized for a minimum of three- and  
 12 four-factor interactions. The numbers of generalized words of lengths 3, 4 and 5, as returned by R, are 0.00,  
 13 0.27 and 0.49, respectively. Consequently, reducing the number of experiments to 72, as compared to 144  
 14 in a full-factorial design, resulted in a well-balanced experimental plan with only slight confounding.

15 The factors and their respective levels are listed below. For the four factors on two levels, the levels were  
 16 0 and 1, which indicate if the respective parameter was included for calibration (1) or not (0).

17 **WRL** weighting factor for the Rayleigh time-step within Equation 10;  $\in [0, 0.5, 1]$ .

18 **SPP** number of Latin hypercube samples per calibration parameter; note that particle density and particle  
 19 to particle rolling friction were always included for calibration;  $\in [3, 6, 9]$ .

20 **MU\_PP** static friction between particle and particle: 0 or 1.

21 **MU\_PW** static friction between particle and wall: 0 or 1.

22 **YM** Young's modulus: 0 or 1.

23 **RF\_PW** rolling friction between particle and wall: 0 or 1.

24 The number of sample locations was determined according to Equation 11, where  $S$  is the number of  
 25 sample locations generated by the Latin hypercube sampling algorithm,  $f_{cal}$  is the number of DoE factors  
 26 included in the calibration and  $SPP$  is the factor from the experimental plan. Note the specification of  
 27  $(f_{cal} + 2)$  in Equation 11: particle density and the rolling friction between particles (RF\_PP) were always  
 28 included for calibration and are therefore omitted from the experimental plan shown in Table B-1.

$$S = (f_{\text{cal}} + 2) \cdot SPP \quad (11)$$

1 If a parameter were used for calibration, its value interval was selected from the pre-defined list in  
 2 Table 2. These intervals were defined by the authors according to published data from experiments and  
 3 DEM simulations with glass beads [34–52]. Recalling subsection 2.3.3, this is a typical situation where  
 4 data from literature are ambiguous and the calibrator knows an approximate range for most of the calibration  
 5 parameters. In order to speed up the computations, the Young’s modulus found in literature was scaled  
 6 down by two orders of magnitude; it was found in preliminary simulations that the results for the angle  
 7 of repose and the bulk density are unaffected by this which agrees with published findings [53]. When  
 8 a parameter was excluded from calibration, its value was set constant. These values were MU\_PP=0.2,  
 9 MU\_PW=0.2, RF\_PW=0.01, YM= $5.06 \times 10^8$  Pa.

10 For each of the single runs specified in the experimental plan in Table B-1, a full calibration process as  
 11 described in subsection 2.3.3 was set up and run on a computer with 12 CPUs. The calibration script  
 12 was given the desired values for the bulk density and angle of repose, as well as the respective calibration  
 13 parameter intervals. The calibration process then took place without any user intervention. The overall  
 14 computation time was approximately 350 hours for all 72 runs.

### 15 **3. Results and Discussion**

16 In general, the calibration procedure worked reliably and led to satisfactory calibration outcomes. Various  
 17 correlations and the effect of the Rayleigh time-step were investigated.

#### 18 *3.1. General Findings Related to the Calibration Process*

19 For all cases both the Kriging and DEM optimization were terminated due to the improvement in the  
 20 objective function being less than specified.

21 The absolute difference between desired and calibrated angle of repose and bulk density for all of the 72  
 22 experiments are depicted in the boxplots in Figure 3. It can be seen that especially the bulk density was  
 23 calibrated very precisely. The angle of repose outcome shows a greater scatter; however at least 75% of the  
 24 runs led to an angle of repose value which was within a maximum tolerance of around 15% of the desired  
 25 value of 22°. To some extent, this greater scatter can be explained by the angle of repose being somewhat  
 26 hard to reproduce in simulations as well as physical experiments. The relative differences of the bulk density  
 27 and angle of repose are similar in magnitude to those which can be expected from physical measurements.

28 These values for the angle of repose and bulk density were obtained by a wide variety of parameter  
 29 sets. Figure 4 depicts a boxplot for each parameter used in the calibration. Values of the particle density  
 30 and Young’s modulus tend to lie at the upper and lower ends of their corresponding intervals, respectively.

1 This is likely due to the influence of the optimization criterion of the Rayleigh time-step, which favors high  
2 particle density and low Young’s modulus values to obtain a large time-step (cf. Equation 1). The static  
3 and rolling friction values between particle and wall (MU\_PW, RF\_PW) are spread out over almost the  
4 entirety of their interval. This indicates that their effect on the calibration process is negligible.

5 The material model and contact law parameters of the Kriging models and the DEM model show almost  
6 perfect correlation. Relevant correlation coefficients are listed in Table 3. This means that the Kriging  
7 meta-models were able to predict the optimal parameters precisely. Table 4 lists the correlation coefficients  
8 between DEM and Kriging for the angle of repose, bulk density and Rayleigh time-step. Bulk density and  
9 Rayleigh time-step agree very well, while the correlation between the angle of repose responses is much lower  
10 at 0.72. This underlines the poor reproducibility of the angle of repose. Overall, the Kriging functions were  
11 able to predict calibration parameter values and calibration target responses reliably and accurately.

### 12 3.2. Multivariate Analysis of Variance Results

13 Using the six calibration parameters as factors and the angle of repose, bulk density and Rayleigh  
14 time-step as responses, a multivariate analysis of variance (MANOVA) was carried out. The underlying  
15 model took into account primary factors as well as two-factor interactions. The variance was analyzed  
16 for the Kriging as well as the DEM data and results are listed in Table 5, where a colon between two  
17 factors denotes their two-factor interaction. The Kriging meta-models show significant effects for all of the  
18 single factors at the  $\alpha = 0.05$  level, but none of the two-factor interactions. This is the main difference  
19 compared to the DEM model, where the two-factor interactions DENS:MU\_PP, DENS:RF\_PP, DENS:YM  
20 and MU\_PP:RF\_PP were also found to be significant while MU\_PW was not. These MANOVA results  
21 again confirm that the Kriging meta-models are a suitable means to predict the behavior of the DEM model.  
22 Nonetheless, the second optimization process, which uses the actual DEM model, is still required to refine  
23 the calibration outcome.

### 24 3.3. Correlations between Friction Parameters used for Calibration

25 Friction values for different pairs of materials are often set equal (e.g., [35, 38]), i.e., setting the values  
26 for MU\_PP equal to those for MU\_PW. This may be due to two reasons. Measured values could be  
27 unavailable or have no physical analogue in the case of rolling friction. Alternatively, it could be an attempt  
28 to reduce the number of calibration parameters and, thus, decrease the complexity of the calibration process,  
29 since satisfactorily calibrating many parameters is difficult with trial-and-error methods. Table 6 shows the  
30 Pearson correlation coefficients between static and rolling friction coefficients of the DEM model. The  
31 largest magnitude of correlation by far was found between MU\_PP and RF\_PP at  $-0.659$ , while all other  
32 correlation coefficients were negligible ( $< 0.25$ ). This indicates that there is no sensible justification for  
33 setting particle–particle and particle–wall friction coefficients equal to each other and that calibration is  
34 required for each single friction value.

### 3.4. Effect of the Rayleigh Time-step Cost Function

This study is the first to actively include the Rayleigh time-step size as a calibration criterion for DEM material model calibration. Figure 5 depicts the effect of the weighting factor, WRL, on the Rayleigh time-step, angle of repose and bulk density. Including the Rayleigh time-step in the optimization (WRL=0.5 or 1) leads to a significantly larger time-step. This is beneficial for further application of the calibrated parameter set, as fewer time-steps will be required to simulate processes of any fixed duration. While the Rayleigh time-step is considerably larger, the angle of repose calibration outcome is not significantly affected. The bulk density is largely influenced by the particle density, so as the weighting factor of the Rayleigh time-step increases, the bulk density similarly increases. This is in agreement with the findings reported by Rackl et al. [28].

Nevertheless, the absolute difference between WRL=0 and WRL=1 is only a few percent for the bulk density. Only two of the specified parameters in Table 2, particle density (DENS) and Young's modulus (YM), affect the Rayleigh time-step. Since the YM significantly influences neither the bulk density nor the angle of repose (cf. second to last paragraph in subsection 2.3.4), its value will thus always tend to favor a large Rayleigh time-step due to the cost function specified in this work. This is supported by the value range for the YM in Figure 4, which clearly shows that the YM was consistently chosen at the lower end of its interval. Thus, the only effective parameter to increase the Rayleigh time-step is DENS which has a much smaller effect on the time-step. The absolute effect of the Rayleigh-related part of the cost function on the Rayleigh time-step would presumably be more dominant if stiffness-related measurement data were to be calibrated and a compromise between stiffness and Rayleigh time-step had to be found.

### 3.5. Efficiency of the Calibration Process

The efficiency of the overall calibration process can be assessed from the number of times the DEM model has to be run. DEM models are typically computationally expensive; to save time during the calibration process, it is desired to achieve the calibration aims with the smallest number of runs possible. In the calibration process described in this study, the number of overall DEM model runs can be expressed as a sum of two phases. The first phase is related to the number of sample points of the Latin hypercube sampling and the related number of runs is known *a priori* through Equation 11. The second optimization phase of the procedure is based on the DEM model. The total number of iterations to find a satisfactory parameter set is only known after the calibration process is complete.

The number of required DEM model runs during the optimization step over the number of Latin hypercube samples per calibration parameter (SPP) is shown on the left of Figure 6. This number varies between approximately 10 and 55. It somewhat decreases with more initial samples for WRL=0 and WRL=0.5 and its dependency on the Rayleigh time-step weighting factor (WRL) cannot be estimated from the present results. In theory, the Kriging meta-models will be able to yield more precise predictions if more samples

1 were used to parametrize them. Hence the number of required optimization runs should decrease as the  
2 number of samples increases, which is supported by the findings for WRL=0 and WRL=0.5. However, the  
3 results for WRL=1 do not show this trend.

4 On the right side of Figure 6, the overall number of DEM model runs is depicted. This equals the  
5 sum of sampling runs and optimization runs and it increases with more initial samples. Thus, even though  
6 the number of required optimization runs decreases with an increased number of samples, this effect is not  
7 large enough to compensate for the increased number of initial sampling runs. Since the smallest amount  
8 of overall runs is obtained from only three samples per parameter, the authors suggest using this value for  
9 the described workflow in the future.

10 The described calibration procedure required an average of 51 DEM model runs to finish, where all  
11 required steps were performed automatically. With an average runtime of six minutes per run, it therefore  
12 took about 5 hours to identify a set of parameters.

13 Figure 7 shows the influence of SPP on the calibration outcome of the angle of repose and bulk density.  
14 There is no significant effect of SPP on the precision of the calibration results. However, this may change if  
15 SPP is reduced below some unknown critical value which depends on the DEM model.

#### 16 **4. Conclusions**

17 The main aim of this study was to demonstrate the usefulness of a novel calibration method for DEM material  
18 model parameters, based on angle of repose and bulk density tests. Various parameter combinations were  
19 tested in a design of experiments in order to assess the influence of the number of initial samples, to evaluate  
20 the influence of considering the time-step within the optimization process and to explore interactions among  
21 the DEM parameters.

22 The calibration method yielded a satisfactory outcome for the angle of repose and bulk density, comparing  
23 with the target values. Moreover, the outcome can be considered very good when taking into account the  
24 typical experimental scatter for the bulk density (approx. 5–10%) and the angle of repose ( $\pm 1^\circ$ – $2^\circ$ ).

25 When the Rayleigh time-step was included in the calibration, the time-step increased significantly, while  
26 the target values of the angle of repose and bulk density were still achieved satisfactorily. This is important  
27 to obtain efficient DEM parameter sets because, for a process with a fixed duration, each increase of the  
28 critical Rayleigh time-step size correspondingly reduces the number of overall required iterations and hence  
29 the computational time.

30 No correlation was found among the friction coefficients. Hence setting pairs of these coefficients to the  
31 same value for the sake of decreasing the parameter count lacks justification, at least with regard to the  
32 angle of repose and bulk density.

33 The results from this paper reveal that there exists a solution space of feasible DEM parameter sets

1 which lead to similar results for the desired calibration targets (angle of repose, bulk density). It was  
2 demonstrated by Rackl et al. [28] that including more target values reduces the variety of parameter sets  
3 of such a solution space. It should be clarified that in order to represent the physical behavior of a bulk  
4 solid, appropriate and sufficient experimental data are required. Calibration should be carried out based  
5 on as many physical experiments as possible. Considering six or more parameters, as done in this study,  
6 renders the often used trial-and-error approach highly inefficient and highlights the need for systematic and  
7 automatized calibration methods.

8 Further research should focus on two major aims. The first aim would be to add more DEM models  
9 to the calibration procedure, e. g., a shear cell or triaxial compression test, and study the effect on the  
10 calibration outcome. Adding more DEM models and corresponding measurement results to the calibration  
11 process will enable the calibrated DEM parameter set to be employed for a wider range of applications. If,  
12 for example, the stiffness behavior is of importance, then a uniaxial compression test might be added. It shall  
13 be noted that calibration is only sensible if the laboratory tests are somewhat representative of the foreseen  
14 application to be simulated. As a second aim, the number of required calibration runs of the DEM models  
15 should be minimized. Apart from the number of initial Latin hypercube samples, there are parameters which  
16 have not been taken into account in this study. For example, the optimization algorithm could be altered,  
17 since numerous DEM model runs can be attributed to gradient computation of the Levenberg-Marquardt  
18 scheme. Another option is to take the measurement error from the bulk material experiments into account  
19 and adapt the tolerance settings of the optimization algorithm accordingly; for example, there is no need to  
20 calibrate the angle of repose as precisely as a few percent if the experimental scatter is  $\pm 10\%$ .

## 21 **Availability of the Calibration Procedure Scripts**

22 The GNU Octave scripts used in this study are scheduled to be released as open-source code after AiF  
23 project no. 18371 N/1 ends in spring 2017.

## 24 **Conflict of Interest**

25 There is no conflict of interest.

## 26 **Acknowledgment**

27 This study received funding by the AiF (no. 18371 N/1), within the program for sponsorship by Industrial  
28 Joint Research (IGF) of the German Federal Ministry of Economic Affairs and Energy based on an enactment  
29 of the German Parliament.

## Appendix A. Angle of Repose Measurement using Image Processing

As shown in Figure 8, the angle of repose  $\alpha$  is generally defined as the angle between the horizontal and the lateral surface of a heap formed under gravity. The basic assumption from continuum theory is that the shape of the heap resembles a cone.

The following prerequisites were necessary to carry out the automatized angle of repose measurements in this study. A sphere of 50 mm diameter was added as a reference to the simulation result of a settled heap, such that it did not intersect with the heap. Two high-resolution bitmap graphics were created from LIGGGHTS, one showing the heap in a top-down view (Figure 9a) and the other in a side view (Figure 9b). For ease of the image processing, the colors were set to black for particles and white for the background; neither the cylindrical container nor the bottom plate were exported into these graphics. The Octave package *image* [54] was used for image processing.

For measuring the angle of repose, the approach described in an FEM standard [55] was adapted. In this standard, the angle of repose is determined based on the heap's diameter and height. Thus, the image processing workflow was divided into two parts. Firstly, the heap's diameter was determined as follows:

1. Read in the top-down view, e. g., Figure 9a.
2. Detect the two largest objects (which are the sphere and the heap) and remove any other objects.
3. Compute the length scale per pixel based in the occupied surface projection of the sphere (a circle) and its known diameter; remove the sphere.
4. Obtain the area of all black pixels left on the image  $A_t$  (which is only the heap), compute the center of this area and use this as the center for a circle with radius  $r_l = \sqrt{A_t/\pi}$
5. Remove any black pixels outside of this circle.
6. Repeat steps 4 and 5 once and obtain an updated radius  $r_t$ . This is done in order to reduce the circle's diameter, because the outer area of the heap is less densely packed with particles, as can be seen from Figure 9a.
7. Using the length scale from step 3, the radius  $r_t$  is converted to millimeters. This new radius  $r_f$  is considered the diameter of the heap.

Determination of the height of the heap was carried out using the steps described below:

1. Read in the side view, e. g., Figure 9b.
2. Detect the two largest objects (which are the sphere and the heap) and remove any other objects.
3. Compute the length scale per pixel based in the occupied surface projection of the sphere (a circle) and its known diameter; remove the sphere.
4. Within the image matrix, find the first and last row holding a black pixel. The difference of these row numbers  $h_t$  equals the heap's height in pixel units.

- 1 5. Using the length scale from step 3, the height  $h_t$  is converted into millimeters, renamed  $h_f$ , and  
2 considered the height of the heap.
- 3 6. To account for the bottom layer of spheres, which were obstructed by the ring around the bottom  
4 plate, 5 mm (particle diameter) were subtracted from  $h_f$  in this study.
- 5 Finally, the angle of repose  $\alpha$  was computed according to Equation A.1.

$$\alpha = \arctan \frac{h_f}{r_f} \quad (\text{A.1})$$

## 6 **Appendix B. Experimental Plan**

- 7 The experimental plan of this study is listed in Table B-1.

Figure 1: Schematic of the three-dimensional simulated system used to measure bulk density and angle of repose.

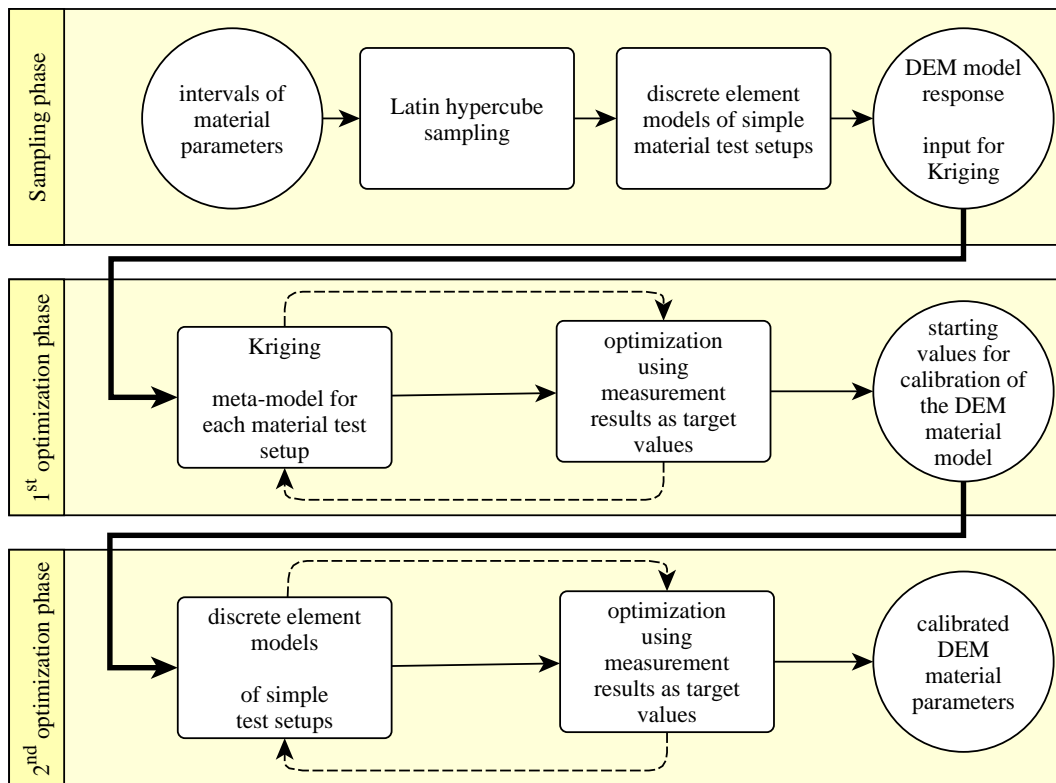

Figure 2: Workflow of the calibration process (adapted from [15]).

Figure 3: Boxplots of the absolute differences between the desired and calibrated angle of repose (AoR) and bulk density (BD).

Figure 4: Boxplots for all calibrated parameters. Outliers are depicted as large black dots, while small gray dots represent the actual values.

Figure 5: Boxplots showing the effect of the weighting factor of the Rayleigh time-step cost function on the Rayleigh time-step (left), angle of repose (middle) and bulk density (right).

Figure 6: Number of required DEM model optimization runs (left) and overall DEM model runs (right) over the number of samples per parameter (SPP), depicted as boxplots.

Figure 7: Boxplots of the effect of the number of samples per parameter (SPP) on the calibration outcome of the angle of repose (left) and bulk density (right).

Figure 8: Side view of a bulk solid heap formed under gravity with the angle of repose  $\alpha$ .

Figure 9: Top-down view (a) and side view (b) of an exemplary heap from the study.

Table 1: DEM input parameters which were fixed for all simulations where p-p is for a particle-particle contact, p-w is for a particle-wall contact and RF is the rolling friction model

Parameter	Value
Poisson's ratio	0.22
Coefficient of restitution (p-p)	0.89
Coefficient of restitution (p-w)	0.60
Viscous damping coefficient of RF (p-p)	0.25
Viscous damping coefficient of RF (p-w)	0.25

Table 2: Set parameter intervals if a parameter is included in the calibration; DENS: particle density.

<b>Parameter</b>	<b>Interval</b>	<b>Unit</b>	<b>Included?</b>
DENS	[2400; 2600]	kg m <sup>-3</sup>	always
MU_PP	[0.1; 0.3]	-	acc. to DoE
MU_PW	[0.1; 0.3]	-	acc. to DoE
RF_PP	[0.001; 0.1]	-	always
RF_PW	[0.001; 0.1]	-	acc. to DoE
YM	[4.175; 6.500]	10 <sup>8</sup> Pa	acc. to DoE

Table 3: Pearson correlation coefficients between DEM optima and Kriging optima for material model and contact law parameters.

<b>Parameter</b>	<b>Correlation coefficient</b>
DENS	0.9465
MU_PP	0.9987
MU_PW	0.9999
RF_PP	0.9999
RF_PW	1.0000
YM	0.9969

Table 4: Pearson correlation coefficients between the response data of the DEM model and Kriging output.

<b>Response value</b>	<b>Correlation coefficient</b>
Angle of repose	0.7186
Bulk density	0.9413
Rayleigh time-step	0.9943

Table 5: MANOVA results; p-values and levels of significance which are indicated at the following  $\alpha$  levels: \*\*\*/0.001, \*\*/0.01, \*/0.05, ./0.1.

<b>Factor</b>	<b>Kriging</b>		<b>DEM</b>
