The laser-heated diamond anyli cell is widely used in the laboratory study of mate-14 rials behavior at high-pressure and high-temperature, including melting curves and 15 liquid properties at extreme conditions. Laser heating in the diamond cell has long 16 been associated with fluid-like motion in samples, which is routinely used to deter-17 mine melting points and is often described as convective in appearance. However, the 18 flow behavior of this system is poorly understood. A quantitative treatment of melt-19 ing and flow in the laser-heated diamond anvil cell is developed here to physically 20 relate experimental motion to properties of interest, including melting points and 21 viscosity. Numerical finite-element models are used to characterize the temperature 22 distribution, melting, buoyancy, and resulting natural convection in samples. We find 23 that continuous fluid motion in experiments can be explained most readily by natural 24 convection. Fluid velocities, peaking near values of microns per second for plausible 25 viscosities, are sufficiently fast to be detected experimentally, lending support to the 26 use of convective motion as a criterion for melting. Convection depends on the phys-27 ical properties of the melt and the sample geometry, and is too sluggish to detect for 28 viscosities significantly above that of water at ambient conditions, implying an upper 29 bound on the melt viscosity of about 1 mPas when convective motion is detected. 30 A simple analytical relationship between melt viscosity and velocity suggests direct 31 viscosity measurements can be made from flow speeds, given basic thermodynamic 32 and geometric parameters of samples are known. 33

37 I. INTRODUCTION

Accurate experimental constraints on melting points and liquid properties in materials 38 under high pressure conditions are needed in fields ranging from condensed matter theory^{1,2} 39 to planetary science³⁻⁵, where high-pressure melts play a central role in magmatism, thermal 40 evolution, and magnetic field generation. For most materials the melting temperature in-41 creases significantly under pressure. This includes fluids such as water⁶ or hydrogen⁷ which 42 solidify under pressure, and solids such as iron^{3,4,8–10} which exhibit significantly elevated 43 melting points. It is thus necessary to reach temperatures on the order of thousands of 44 degrees Kelvin in experiments at pressures of tens to hundreds of GPa to study melting and 45 the properties of fluid phases. 46

The diamond anvil cell (DAC) has been an instrument of unparalleled utility in the 47 laboratory study of matter at high pressure and temperature. Studies using this device 48 have paid special attention to the characterization of phase transitions, and in particular, 49 to melting. External heating of the DAC using resistive heating can reach temperatures of 50 roughly 1000 K in samples, below melting temperatures for many materials under pressure. 51 In contrast, laser heating of the diamond cell – i.e. localized, direct laser illumination of high 52 pressure samples through the diamond optical window – can achieve maximum temperatures 53 exceeding 10 000 K,^{11,12} enough to melt all known materials to very high pressures.^{1,4,5,13–17} 54 This laser-assisted DAC setup is called the laser-heated diamond anvil cell (LHDAC). 55

While providing the capability of studying high-pressure melting and melts in virtually all 56 substances, LHDAC techniques are often complicated, compared to homogeneous external 57 heating, by very large standing temperature gradients in samples, on the order of hundreds 58 to thousands of degrees K per micron.^{9,10,12,18–31} Local pockets of melt can be stabilized in 59 these temperature gradients, surrounded by lower-temperature solid matter and the cold, 60 heat-sinking diamond anvils. The accurate detection of melting in such experiments is a 61 longstanding challenge in high-pressure research. There is also a pressing need to determine 62 the properties of the fluid state, including viscosity. 63

Among the most common^{3,8-10,19,32-41} and controversial^{1,4,14-17,42-44} diagnostics of melting in LHDAC experiments is the visual observation of motion in the laser-heated sample, which is attributed to fluid flow and often described as being 'convective' and 'continuous' in appearance.^{3,9,32,34,36-42} While this motion is readily observable in experiments, there is

limited understanding of the nature and origin of the motion, and thus how it is connected 68 to melting in the LHDAC. Sample motion has been usually characterized by qualitative 69 criteria,^{3,9,10,19,32,34,36–40,42} adding significant uncertainty to experimental interpretations. If, 70 as qualitatively assessed, observed motions are convective in nature, then it stands to reason 71 that these motions, coupled to information about temperature gradients and sample geom-72 etry, will enable assessment of fluid transport properties, and in particular viscosity. This 73 information is also needed to assess systematic differences between melting studies. Motion-74 based criteria have yielded melting curves consistent with other approaches in many cases, 75 for example in bridgmanite^{32,42,45}, sodium chloride^{14,33} and aluminum¹ but pronounced and 76 as-yet unresolved discrepancies in others, as in iron^{3,4}, tantalum^{16,35,44} and molybdenum.^{15,35} 77 In this study we address this gap in knowledge by quantitatively relating melting and motion 78 in the LHDAC, establishing its underlying physical basis and assessing possible observable 79 phenomena in experiments which may signal the cause of the flow and the character of the 80 fluid state. 81

In the past, order-of-magnitude considerations have been applied to estimate possible causes of fluid flow in the LHDAC, rates of flow, and the effects of flow on heat transport and temperature distributions.^{19,21,28} Assuming that flow is convective, and driven by the temperature gradients across fluid regions, which produce buoyancy, several estimates regarding flow properties can be made through dimensional analysis.⁴⁶

In free (also called natural) convection, the Grashof number Gr establishes the relative importance of buoyant, viscous, and inertial forces. It is defined as

89

$$Gr = \frac{g\rho^2\beta\Delta TD^3}{\mu^2},\tag{1}$$

where g is the acceleration of gravity, ΔT is the temperature difference across the characteristic length scale of the fluid D, and ρ , β and μ are the material density, volumetric thermal expansivity, and dynamic (also called shear) viscosity, respectively. On the microscopic scale of the LHDAC the D³ factor dominates, such that Gr << 1 is a good approximation. This implies that inertial forces are small compared to viscous forces, which balance the buoyant forces, giving a characteristic flow velocity U of^{21,46}

96
$$U \approx \frac{\rho g \beta \Delta T D^2}{\mu}.$$
 (2)

⁹⁷ This is equivalent to stating that the ratio of inertial force to viscous force, or Reynolds

 $_{98}$ number Re, given by

99

$$Re = \frac{U\rho D}{\mu},\tag{3}$$

100 is equal to Gr,

101

$$Gr \approx Re.$$
 (4)

Assuming liquid properties similar to water, a typical liquid dimension $D \approx 1 \, \mu m$, and a tem-102 perature gradient of $\sim 10^3 \,\mathrm{K\,\mu m^{-1}}$, then $Gr \approx 10^{-6}$ and $U \approx 1 \,\mu\mathrm{m\,s^{-1}}$. Speeds within several 103 orders of magnitude of this value are expected for a realistic range of material properties 104 and sample geometries. Such speeds would be consistent with detectable convective motion 105 seen under microscopy in real time in experiments. However, this estimate is crude in that 106 it does not account for the specific geometry of the LHDAC, the flow planform and position-107 dependence of velocity, the detected component of velocity, and other specific aspects of 108 experimental systems. It has been reported³⁷ that the character and vigor of convection 109 in the LHDAC sample chamber is noticeably sensitive to "the sample itself, the pressure 110 medium, pressure, temperature, pressure-temperature gradients, and chamber geometry", 111 and so is dependent on a complex interplay of sample properties, which are accounted for 112 in this study. 113

When considering the character of convection and its influence on heat transport, we can also define the Rayleigh number Ra,

$$Ra = \frac{\rho g \beta \Delta T D^3}{\kappa \mu},\tag{5}$$

which may be obtained by multiplying Gr and the Prandtl number $Pr = \mu/\rho\kappa$ (the ratio 117 of viscous diffusivity μ/ρ to thermal diffusivity κ). At $Gr \ll 1$, Ra is also equivalent to 118 the ratio of convective heat transfer to conductive heat transfer.⁴⁶ For the representative pa-119 rameters of the LHDAC discussed above, $Ra \approx 10^{-6}$, and for any realistic set of parameters 120 in the LHDAC $Ra \ll 10^3$, roughly the critical value of Ra in ideal systems below which 121 convection is inhibited.^{19,21} These considerations have been argued to lead to absent¹⁹ or 122 sluggish²¹ buoyancy convection and a correspondingly negligible effect of convection on heat 123 transfer in the LHDAC.^{19,21,28} A complete quantitative consideration of these dynamics is 124 explored in this study. 125

¹²⁶ Numerical models have been used extensively to describe phenomena relevant to the ¹²⁷ laser-heated diamond cell, including temperature distributions^{12,18,20–31,47} and, to a limited

extent, melting,^{12,27,28} however fluid flow has not been directly modelled. In this paper, we 128 present numerical finite-element models of natural thermal convection in the LHDAC, having 129 a two-dimensional (axisymmetric) spatial geometry and axial orientation of gravity. We use 130 time-dependent finite-element algorithms solving for thermal transport in the LHDAC (e.g. 131 Montova and Goncharov²⁷), and include a Boussinesq fluid medium governed by the Navier-132 Stokes equations. Temperature gradients, sample physical properties, the occurrence of 133 melt-solid boundaries inside heated samples, and the detailed configuration of typical sample 134 chambers are accounted for by these numerical models of flow. Simulated samples, containing 135 a solid metallic coupler on which laser energy is deposited, are fully fluid or locally melted by 136 laser heating, with the melt boundary and location of melt determined self-consistently with 137 the temperature gradient. Flow speed is found to be strongly controlled by fluid viscosity and 138 by the particular geometry of the LHDAC. Maximum simulated flow velocities are at most 139 small (of the order of tenths of $\mu m s^{-1}$ for water-like viscosity), though are sufficiently fast to 140 be observed in the laboratory. Natural thermal convection is thus confirmed to be possible 141 in the LHDAC, though order of magnitude estimates of flow behavior discussed above have 142 limited utility, revealing a need for detailed experimental models. The analysis of natural 143 convection in the LHDAC developed here provides a reference model for flow and the forces 144 that drive it, from which we consider possible alternative causes for flow and other types of 145 motion that may occur in experiments. Ultimately, these models allow for a quantitative 146 evaluation of experimental observations. Results are discussed in the context of motion 147 observations previously made in LHDAC experiments and those that could potentially be 148 made, such as velocity mapping of molten samples. 149

The simulation parameters and the equations of motion and energy are found in Section II. The model results in the steady-state limit are presented in Section III. Section IV discusses the physical and practical implications of the models and their relationship with prior work. A summary of conclusions drawn from our simulations and a discussion about future investigations is included in Section V.

155 II. METHODOLOGY

156 A. GEOMETRY

A DAC consists of two gem-cut diamonds pressed together at their culets, flat tips having 157 a radius R_d on the order of tens to hundreds of μm . There is a gasket, a foil that is placed 158 between the culets of the diamonds where a hole (of radius $R_m < R_d$) is cut. This gasket 159 holds the sample inside the hole and between the two diamonds. To study transparent 160 samples in the LHDAC, such as water, a thin metallic (or other optically absorptive) foil, 161 known as the coupler (of radius $R_c < R_m$), is often introduced into the sample cavity to 162 absorb laser radiation. To study opaque samples, such as Fe, a transparent pressure medium 163 is placed around a foil in essentially the same configuration, with the medium acting as an 164 insulator. The coupler may be held in place away from the diamond with grains of ruby 165 or other material placed between the culet and the coupler. Melting of the medium or the 166 coupler may be studied.¹⁰ Optical access to the sample chamber is provided through the 167 anvils. 168

The system modeled in this study represents this typical set up of a LHDAC experiment 169 (Fig. 1). The modeled domain comprises a metallic coupler disk and a surrounding optically 170 transparent pressure medium. The coupler is placed in the center of the cavity, and the 172 medium is contained by the diamonds (on top and bottom) and gasket (laterally). The 173 acceleration of gravity is set parallel to the DAC axis, which runs through the center of the 174 culets, cavity and coupler. Assuming this geometry and laminar flow, the problem to solve 175 is axisymmetric, i.e. there are no forces that would change the motion with respect to the 176 angle ϕ , measured on the surface perpendicular to the axis. This common experimental 177 geometry is convenient for numerical models and minimizes calculation time. Once this 178 symmetry is assumed, the nominally 3D problem of flow becomes a 2D problem where there 179 are variations only in r, distance to the axis, and z, position in the axial direction, as a 180 function of time. The case of a horizontal axis (perpendicular to gravity), another common 181 experimental configuration, must be modeled using all three spatial dimensions, presenting 182 a more challenging problem not addressed here. 183

The coupler is heated on surfaces s_1 and s_2 by axially-aligned laser beams incident from top and bottom, and having equal power. This is a typical 'double-sided' laser heating

FIG. 1. This figure shows the schematic configuration of the modelled domain. We assumed a cylindrical symmetry around the axis shown in purple. The coupler disk (orange) is made of an optically opaque material and is heated with lasers on surfaces s_1 and s_2 , shown in green. Inside the sample cylinder (white) the pressure medium is optically transparent and it is heated only by the heat transferred from the interior disk. Outer boundaries of the sample chamber are kept at a constant temperature of 300 K.

¹⁸⁶ configuration. We used the dimensions of a typical DAC, and of lasers currently used ¹⁸⁷ in LHDAC systems (see Table I). We assumed an ambient temperature ($T_{min} = 300 \text{ K}$) ¹⁸⁸ boundary condition at the edges of the sample chamber, a good approximation for the ¹⁸⁹ LHDAC.^{18,20,25,27,28,30}

TABLE I. Geometrical parameters used in the models. The LHDAC sample cavity is a cylinder of radius R_m and height H_m . The coupler is located at the center of the space and defined as a cylinder of radius R_c and height H_c , a distance $d = (H_m - H_c)/2$ from the diamond culets. The laser heating spots on the coupler have a radius parameter ℓ .

190 191

In our models we treat melting of the transparent pressure medium and assume that the coupler remains solid. This is the configuration used to study dielectrics melting, as applied in many of the more reliable studies using motion-based melting curve determination ¹⁹⁵ (MgSiO₃^{32,42,45} and NaCl^{14,33} were mentioned earlier). The coupler is presumed to remain ¹⁹⁶ fixed in place, even when the surrounding medium is entirely fluid. For simplicity, we neglect ¹⁹⁷ any other material in the DAC other than the coupler and the medium.

198 B. PHYSICAL PROPERTIES OF MATERIALS

¹⁹⁹ Material properties used in the simulations are representative of materials commonly ²⁰⁰ studied in the laser-heated diamond anvil cell (Table II). The medium was selected to have

TABLE II. Physical properties of the materials used in the simulations: mass density (ρ) , heat capacity at constant pressure (C_p) , thermal conductivity (k), thermal diffusivity $(\kappa = k/\rho C_p)$, emissivity of the coupler (ϵ) and volumetric thermal expansion coefficient for the liquid phase (β) . Values of medium viscosity (μ) and melting temperature (T_{melt}) , were varied systematically for different simulations.

201 202

physical properties similar to those of water in the range of 0-15 GPa, for fluid density 203 ρ , heat capacity C_p , thermal conductivity k, and volumetric thermal expansivity β . In 204 order to do a parametric study, we systematically varied selected properties of the medium 205 which were found to have a first-order effect on flow behavior in the simulations, specifically 206 the melting temperature (T_{melt}) , which controls melt volume, and the melt viscosity (μ) . 207 Melt viscosities $\mu = 10^{-5}$, 10^{-3} , 0.1, 10, and 10^3 Pas were tested. This range of values 208 covers very low viscosity fluids such as liquid hydrogen ($\sim 10^{-5} \text{ Pas}$), water ($\sim 10^{-3} \text{ Pas}$), 209 and silicate melts ($\sim 10^3 \text{ Pa s}$). Medium melting temperatures $T_{melt} = 300, 400, 1000, \text{ and}$ 210 2000 K were tested in primary simulations ($T_{melt} = 350$ and 1500 K were also tested in 211 earlier simulations, partial results of which are presented here). We assume that physical 212

properties of the medium in liquid and solid states are identical, and that the medium is
always optically transparent. The coupler is assumed to have properties similar to metals
used in such experiments, specifically iron.

216 C. GENERAL SIMULATION METHODOLOGY

In order to describe the dynamical behavior inside the DAC under various heating conditions we used a finite-element solution of the time-dependent energy transfer equation

²¹⁹
$$\frac{\partial T}{\partial t} = -\mathbf{u} \cdot \nabla T + \kappa \nabla^2 T, \tag{6}$$

where T is the temperature, t is the time, and **u** is the flow velocity (with corresponding speed $v = |\mathbf{u}|$). For the solid, there is no flow and $\mathbf{u} = 0$. For the liquid region it is necessary to solve simultaneously the full Navier-Stokes equations

223
$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla)\mathbf{u} = -\frac{\nabla P}{\rho} + \frac{\mu}{\rho}\nabla^2 \mathbf{u} + g\beta T \hat{\mathbf{z}}, \tag{7}$$

where P is the pressure and $g\hat{\mathbf{z}}$ is the downward acceleration of gravity. We used the solution for a Boussinesq fluid, where the changes in density are small and proportional to T, so the continuity equation reads as:

227

234

$$\nabla \cdot \mathbf{u} = 0. \tag{8}$$

Densities are assumed to remain constant throughout simulations and upon solid-liquid phase change; for the solid this means that thermal expansion effects are neglected; for the fluid, this means that thermal expansion is accounted for only through the Boussinesq approximation.

The heating lasers are assumed to have a Gaussian spatial intensity distribution $\mathcal{I}(r,t)$ at the coupler surface of

$$\mathcal{I}(r,t) = \frac{\epsilon \mathcal{P}(t)}{\pi \ell^2} \exp\left(-\frac{r^2}{\ell^2}\right),\tag{9}$$

where $\mathcal{P}(t)$ is the power of the laser, ℓ defines the radius of the laser spot, and ϵ is the surface emissivity. The heating is modeled to be continuous in time (i.e., $\mathcal{P}(t) = \mathcal{P}_o$), by raising the power in the first few 10^{-8} s of the simulation.

The simulations are initialized with all the cavity at ambient temperature (300 K), and flow velocities $\mathbf{u} = 0$. At t = 0 the laser is turned on, and the model develops the heat transfer and fluid motion out of equilibrium while heating the surfaces s_1 and s_2 of the ²⁴¹ coupler. In each simulation, the temperature and velocity distribution are allowed to evolve
²⁴² to a steady state.

The temperature distribution in the sample is found to be identical whether or not flow 243 terms are included in the simulations, confirming that heat advection does not contribute 244 significantly to the heat transport in the case of natural convection, as expected from dimen-245 sional analysis. This fact allows for several simplifications in the models. Most importantly, 246 the position of the solid-melt boundary is defined only by heat conduction, and so can be 247 assessed a priori in simulations without the need to define it self-consistently with the flow, 248 a significantly more challenging problem. Also, for all simulations at given \mathcal{P}_o , the maximum 249 temperature T_{max} is effectively constant. Radiative contributions to heat transport are also 250 negligible compared to the conductive contributions.^{28,30} 251

The simulations were performed as follows. First, at a given \mathcal{P}_o , a simulation was run 252 with two model domains (coupler and medium) assuming the medium was fully liquid 253 $(T_{melt} = T_{min} = 300 \,\mathrm{K})$ with water-like viscosity $\mu_w = 10^{-3} \,\mathrm{Pa\,s.}$ This established a ref-254 erence temperature distribution at this laser power. Next, a sequence of simulations at 255 various values of μ and T_{melt} were performed. The solid-liquid boundary was identified by 256 the isothermal contour in the reference temperature distribution corresponding to the melt-257 ing temperature T_{melt} , which was used to divide the medium into solid and liquid domains 258 producing a new geometry of three domains (coupler, solid medium, and liquid medium), 250 as is appropriate for congruent melting.²⁸ To check the validity of this approach, the new 260 location of the T_{melt} isotherm in the final simulation was compared with that in the refer-261 ence simulation $(T_{melt} = 300 \text{ K}, \mu_w)$, and the difference in isotherm position was found to be 262 negligible. The sequential approach followed is thus physical for describing partial melting 263 in the steady state limit. 264

The steady state was evaluated by observing flow velocity approach an asymptotic limit (Fig. 2). The time needed to reach steady-state equilibrium in the simulations is in the range of 10 µs to 5 ms. It is longest for the lowest viscosities, because the viscous diffusion time, τ_{μ} , given as

270

$$\tau_{\mu} \approx \rho D^2 / \mu, \tag{10}$$

is larger for lower viscosity, approaching $\sim 3.6 \text{ ms}$ for $\mu = 10^{-5} \text{ Pa s}$. For all other viscosities, viscous diffusion times are very rapid, and the equilibration is mainly controlled by the

FIG. 2. Maximum velocity versus time for $T_{melt} = 300 \text{ K}$, $T_{max} = 5051 \text{ K}$ and $\mu = 10^3$, 10^1 , 10^{-1} , 10^{-3} , and 10^{-5} Pas for blue, green, red, purple and cyan color lines, respectively. For the lowest viscosity, equilibrium is not achieved on the timescale of this plot. In the case of higher viscosities (bottom curves), the steady state is reached after $\tau_{\kappa} \approx 13 \,\mu\text{s}$; for low viscosity (top curve) steady state is not reached until $\tau_{\mu} \approx 4 \,\text{ms}$.

²⁷³ thermal diffusion time τ_{κ} , given as

274

 $\tau_{\kappa} \approx D^2 / \kappa, \tag{11}$

which is $\sim 13 \,\mu\text{s}$. Thus the approach to steady state equilibrium in the simulations is controlled by the longer of τ_{μ} and τ_{κ} .

In most simulations reported here, we defined the solid-melt boundary in the medium 277 by a direct interpolation of the isothermal contour in the temperature distribution. In an 278 earlier set of simulations, we used a simplified definition of the melt boundary defined by an 279 ellipsoidal function, which approximated the shape and position of the solid-melt interface. 280 This analytical boundary allowed for a faster numerical convergence, but generally showed 281 more significant errors in defining the melt vesicle. Nonetheless, these results were found 282 to be in good agreement with later, more accurate simulations in terms of scaling behavior 283 (Section IIIB), indicating that the details of the shape of the melt package are not very 284 significant for estimating the steady-state flow behavior. 285

286 D. LATENT HEAT EFFECTS

When the laser is turned on, the system heats up reaching a maximum temperature at 287 the center of the coupler's surface T_{max} (r = 0 and $z = \pm 2 \,\mu\text{m}$). When $T_{max} > T_{melt} > T_{min}$, 288 a phase boundary must be created in the medium. Phase change generally requires the 289 inclusion of a latent heat term in the thermal balance. We included the latent heat using 290 the apparent heat capacity method (AHCM),⁴⁸ assuming a smooth transition from one 291 phase to the other (and the presence of a mushy region), with g_l and g_s specifying the liquid 292 and solid volume fractions, respectively. Considering heat conduction only $(\mathbf{u} = 0)$, the 293 numerical algorithm solves 294

$$\frac{\partial H}{\partial t} = \nabla \cdot (k_a \nabla T), \tag{12}$$

(13)

where H is the enthalpy, and the apparent thermal conductivity $k_a = g_s k_s + g_l k_l$, where k_s and k_l are the thermal conductivities of the solid and liquid phases respectively. This method uses an apparent heat capacity

$$c_a = \frac{dH}{dT},$$

300 where

295

299

301

307

$$H = g_s \int_{T_{ref}}^T \rho_s C_s d\theta + g_l \int_{T_{ref}}^T \rho_l C_l d\theta + \rho_l g_l L, \qquad (14)$$

³⁰² such that L is the latent heat and T_{ref} is an arbitrary reference temperature; C_s , ρ_s and ³⁰³ C_l , ρ_l are the heat capacities (at constant pressure) and densities from the solid and liquid ³⁰⁴ phases, respectively. The apparent heat capacity (per unit volume) is then written as

$$c_a = g_s \rho_s C_s + g_l \rho_l C_l + \left(\int_{T_{ref}}^T (\rho_l C_l - \rho_s C_s) \, d\theta + \rho_l L \right) \frac{dg_l}{dT}$$
(15)

³⁰⁶ The numerical implementation thus solves the equation

$$c_a \frac{\partial T}{\partial t} = \nabla \cdot (k_a \nabla T). \tag{16}$$

In order to assess the effect of the latent heat, we again used the parameters in Table II for both liquid and solid phases, resulting in $c_a = \rho(C_p + L dg_l/dT)$ and $k_a = k$, such that outside the transition $c_a = \rho C_p$ [i.e. Eq. (16) is equivalent to Eq. (6)] and during the transition $c_a = \rho C_p + \rho L/\Delta T$. The melt fraction $g_l = 1 - g_s$ is assumed to increase with T from 0 to 1 at T_{melt} over an interval of $\Delta T = 1$ K. This step-like function approximates congruent melting.²⁸ In this case, the only signatures of the phase change in the simulation will be those directly due to the latent heat. Choosing a value for the latent heat to be L = 300 kJ/kg (similar to water ice melting) we solved the finite element model and compared it to the solution with L = 0 (Fig. 3). We observe that when latent heat was accounted for the maximum

FIG. 3. Effect of latent heat of melting. Models with latent heat L = 0 and L = 300 kJ/kg are compared, for maximum laser power, $T_{melt} = 400$ K, and neglecting fluid flow. A, time series of the temperature at the center of the coupler surface. The temperature grows faster for L = 0 (solid line) than for L > 0 (dashed line), but reaches the same equilibrium value. B, temperature profiles through the axis of the DAC from the center to the culet for four different snapshots at t = 5, 10, 20, and 1000 µs, for L = 0 (solid lines) and L = 300 kJ/kg (nearby dashed lines).

318

319

temperature is reached later than in the case of L = 0. However, both simulations reach identical maximum temperatures in the steady state limit. It is also possible to observe that the temperature distribution over the DAC axis (Fig. 3B) depends on latent heat at earlier times but is identical later in the simulation. This can be expected since $\partial T/\partial t$ vanishes when the steady state is reached, and the solution of Eq. (16) becomes independent of L. Thus latent heat has no effect on temperatures for steady-state conditions.

326 III. RESULTS

327 A. GENERAL OBSERVATIONS

All models develop temperature profiles that are symmetric about a horizontal plane through the center of the sample, due to use of double-sided laser illumination (Fig. 4A), with T_{max} reached at the axial point on the illuminated surfaces. For all models T_{min} is constant but the change in laser power changes T_{max} and the isothermal contours, and thus melt vesicle shape and size for a given T_{melt} . The solid:liquid volume ratio in the medium ranged from zero (fully molten medium, $T_{melt} = 300$ K) to 0.995 (having two small melt vesicles at the laser-heated spots).

The steady state flow we find for the simulations has a constant general geometry. For 335 the fully fluid runs $(T_{melt} = 300 \text{ K})$ three convection cells develop, with one forming away 336 from the coupler at the sample edge (Fig. 4B); maximum velocities are found next to the 337 coupler's outside edge (Fig. 5) and have an upward axial direction. Where the pressure 338 medium is partially melted $(T_{melt} > 300 \,\mathrm{K})$, there are two main convection cells where 339 maximum velocities are directed radially inward (outward) for the sample above (below) the 340 coupler (Fig. 4C-E). Maximum flow velocity is located in a ring $\sim 1 \,\mu m$ above and below the 341 coupler with a radius of several μm (Fig. 5). 343

The flow and the maximum velocity are given by pressure imbalances due to the strong 344 thermal gradients and resulting buoyant forces. There is a correlation between maximum 345 velocity and differential pressure across the fluid, as well as melt geometry (Fig. 6). Both 346 maximum velocity and maximum pressure difference are larger for larger values of T_{max} 347 and lower values of T_{melt} . Models with a fully fluid medium (lower part of Fig. 6A) and 348 a convection pattern with a dominant cell away from the coupler (Fig. 4B) show larger 349 velocities (by a factor of ~ 2) than models with partial melting and fluids confined close to 350 the coupler (upper part of Fig. 6A). This is due to a shift in the planform of convection rather 351 than to a change in driving pressure, which scales gradually with T_{max} and T_{melt} (Fig. 6B). 352 The maximum pressure difference across the fluid region is 0.036 Pa, for the largest T_{max} 353 and lowest T_{melt} , i.e. for fully liquid medium and highest peak temperature. That is, the 354 larger the fluid volume and temperature variance, the larger the pressure difference across 355 the volume resulting in faster flow speeds (Fig. 7). 350

FIG. 4. Axisymmetric cuts of temperature and velocity magnitude for $T_{max} = 2675$ K. A, temperature map; color indicates temperature; white, grey, and black lines are isothermal contours for 400, 1000, and 2000 K, respectively. B, C, D, and E, velocity maps for $T_{melt} = 300$, 400, 1000, and 2000 K, respectively; color indicates speed, with $v_{max} = 0.337$, 0.159, 0.0518, and $1.93 \times 10^{-3} \,\mu\text{m s}^{-1}$, respectively, for μ_w (10^{-3} Pas); black lines show the flow streamlines with arrows indicating the direction of the flow.

358 B. SCALING BEHAVIOR

The velocities found at a given T_{melt} and T_{max} (i.e. for a given melt geometry) scale in direct proportion to viscosity (Fig. 8). Setting a reference value for viscosity to be $\mu_w =$ 10^{-3} Pa s, if a corresponding velocity is v_w , we find that for simulations differing only in the assumed value of viscosity the velocity generally scales as $v = (\mu_w/\mu)v_w$. Model results for velocity presented here at this reference viscosity (i.e., Figs. 4 to 7 and 10B) can be

FIG. 5. Location of maximum velocity in the upper half of the sample (bottom half is symmetric). Colors indicate the velocity magnitude for μ_w . The symbols represent $T_{melt} = 300, 400, 1000$, and 2000 K for \circ , \Box , \bigtriangledown , and \diamond , respectively. At maxima locations above the coupler, flow is radially directed; for maxima outside the coupler ($T_{melt} = 300$ K) flow is axially directed.

FIG. 6. Contours of A, maximum flow velocity (v_{max}) and B, maximum pressure difference across the fluid (ΔP) as a function of T_{melt} and T_{max} , for μ_w . Velocities at other viscosities can be accurately obtained by multiplying values in A by the ratio of μ_w/μ , whereas ΔP is identical for all μ . A is separated into two zones depending on the location of the velocity maxima: vertical lines at $T_{melt} = 300 - 400$ K correspond to a fully fluid case $(T_{melt} = 300 \text{ K})$ and contours at $T_{melt} = 400 - 2000$ K are for partial melting $(T_{melt} \ge 400 \text{ K})$.

FIG. 7. Plot of maximum velocity versus the characteristic flow length-scale (D) for μ_w . The symbols correspond to simulations with $T_{melt} = 300, 400, 1000, \text{ and } 2000 \text{ K}$ for \circ, \Box, ∇ , and \diamond , respectively. The colors correspond to T_{max} in the color bar.

accurately adjusted to describe other viscosities using this scaling relationship.

FIG. 8. Scaling of peak velocity v_{max} with viscosity μ for a series of simulations at fixed melt volume as shown in Fig. 4E ($T_{max} = 2675 \text{ K}, T_{melt} = 2000 \text{ K}$).

Following Section I we expect that for the present experimental system $Re \simeq Gr$ should provide a good approximation for the dynamics. Indeed, one of the key predictions of this model is the inverse proportionality of v_{max} and μ [Eq. (2)], as seen in the simulations (Fig. 8). We therefore calculated Re and Gr for our dataset to compare with the predictions

of dimensional analysis. Given the geometry of this system (Fig. 9A) and our approximation 369 that the thermal conductivity of the medium is constant and identical in solid and liquid, 370 the axial temperature gradient in the medium is linear (Fig. 9B), and we may transform 371 Re and Gr into known (measurable) parameters in our experimental setup: the maximum 372 temperature, T_{max} , located on the axis of symmetry; the melting temperature T_{melt} ; the 373 minimum temperature T_{min} corresponding to the anvil surface; and the thicknesses of the 374 medium d and the melt D along the axis. Hence D is the characteristic length scale of the 375 fluid vesicle. The temperature difference across the liquid zone is then 376

FIG. 9. Simplified geometry of a laser-heated diamond cell. A, the LHDAC configuration. B, a 1D view along the axis of symmetry. Panel A highlights the region of interest (R.O.I) around the axis of symmetry corresponding to the temperature distribution in B.

$$\Delta T = T_{max} - T_{melt} \tag{17}$$

380 and

381

379

$$D = \frac{T_{max} - T_{melt}}{T_{max} - T_{min}}d\tag{18}$$

With these definitions, we plotted Re versus Gr, assuming $U = v_{max}$ (Fig. 10).

The dynamic behavior thus obtained follows a relationship $Re \propto Gr$, previously suggested by the dimensional analysis [Eqs. (2) and (4)], but Re and v_{max} for any given Gr are lower than expected by roughly three orders of magnitude. We can represent the results, for any given set of conditions, using a proportionality factor A, i.e.

$$Re = A Gr, \tag{19}$$

FIG. 10. Reynolds number Re versus Grashof number Gr for the complete set of model results. The colors and color bar correspond to the characteristic length scale (D) for each simulation. The solid black line is the fit to the relation Re = A Gr [Eq. (19)], taking A as a constant. The grey line is the upper bound²¹ on Re [Eq. (4)]. The circles represent simulations that used the isothermal contour at T_{melt} to define the solid/liquid boundary while the triangles are simulations that used an ellipsoidal function to estimate the boundary position. Panel A shows all simulation results; the fit of Eq. (19) to these data gave $A = 1.23 \times 10^{-3}$. Panel B shows only results from simulations with μ_w , from the grey region of A.

where A is found to be approximately constant, with the total set of simulations obtained closely described with a value of $A = 1.23 \times 10^{-3}$. This is consistent with the expectation that Eq. (2) provides an upper bound ($A \le 1$) for velocity in the system.²¹

The value of A is insensitive to the specific geometry and size of the fluid region: it is nearly the same for complete melting (Fig. 4B) as for local melting confined to near the laser hotspot (Fig. 4E). Some higher-order deviations from a fixed A are evident, such as weakly decreasing A with melt volume (Fig. 10B). In general, different geometries for specific experimental set ups yield different values of A, sensitive to relative axial and radial dimensions, laser spot size, the orientation of gravity, and other assumed characteristics of the system.

While the prior analysis followed from the assumption that $Gr \ll 1$ and hence $Re \propto Gr$ 398 for the LHDAC, we find $Gr \gtrsim 1$ at the upper limit of the simulated range (Fig. 10A). At 399 such conditions, dimensional analysis implies the inertial contribution to the force balance 400 should become non-negligible, manifesting as a different scaling law⁴⁶ similar to $Re \propto \sqrt{Gr}$. 401 However, in our simulations there is no evidence for a deviation from the linear relationship. 402 This is likely due to the inertia being smaller than expected from dimensional arguments. 403 The scaling laws obtained here thus remain approximately valid throughout the realistic 404 parameter space of the LHDAC. 405

Combining Eqs. (17) to (19), the maximum fluid velocity in the liquid medium can be described by

$$v_{max} = A \lambda \frac{d^2}{\mu} \frac{(T_{max} - T_{melt})^3}{(T_{max} - T_{min})^2},$$
(20)

409 where

410

$$\lambda = \rho g \beta \tag{21}$$

⁴¹¹ is a constant from the physical properties of the material.

While coupler melting was not included in the simulations, coupler and medium melting share a number of similarities that allow some predictions regarding convective flow in the coupler. In the limit of small melt volume, melt vesicles in the coupler and medium have similar size and shape,¹⁰ similar boundary conditions (i.e. $T_{melt} \leq T \leq T_{max}$), and are expected to exhibit similar flow planform given that flow is symmetric for vesicle inversion (Fig. 4D-E). With these similarities, the relationship Re = AGr [Eq. (19)] should also hold 418 for coupler melting, with similar values of A, and may be expressed as

$$v_{max} = A \lambda \frac{D^2}{\mu} (T_{max} - T_{melt}).$$
(22)

Together with the earlier conclusion that flow systematics depend little on the particular 420 geometry of liquid regions, we conclude that a simple scaling law, similar to Eq. (22), 421 generally describes the thermal convective flow within melts in the LHDAC. Another scenario 422 that likely follows these systematics is that of direct laser heating and melting of a semi-423 transparent medium.^{6,21} However, cases where both medium and a coupler melt could be 424 potentially more complicated: while the above law [Eq. (22)] would plausibly hold for minor 425 interfacial deformations observed in such experiments that preserve the basic shape and 426 size of the melted region,^{44,49} larger distortions including hole and droplet formation and 427 multiphase mixing,⁵⁰ and associated surface tensions (see Section IV), could significantly 428 alter flow behavior. 420

430 IV. DISCUSSION

419

The well-defined relationship between viscosity and convective flow speeds in the LHDAC 431 suggests velocimetry as a means to establish viscosity in convecting fluids under pressure. At 432 fixed size of melt, velocities are inversely proportional to viscosity [Eq. (22) and Fig. 8], and 433 so can vary by many orders of magnitude over the plausible range of viscosities encountered 434 in fluids. Velocities also increase by orders of magnitude (at constant viscosity) with the 435 size of the molten region (Fig. 7), which is controlled by initial sample dimensions, melting 436 temperature, and peak temperature, and may be estimated from these known parameters 437 [e.g. Eq. (18)] or through direct observation. Velocity is also linearly dependent on density 438 and thermal expansivity, but given that these are well constrained and relatively invariant 439 under pressure, their uncertainty should not play a major role in viscosity determination. 440 Thus, viscosity and melt dimensions are the primary variables determining the convective 441 flow behavior for any given sample configuration, with the latter being independently mea-442 surable. There are hence good prospects for measuring high-pressure viscosity if convection 443 in the LHDAC can be observed and characterized. 444

It is evident that while thermal convective flow is possible in the LHDAC, it is more sluggish than previously predicted²¹ and may be challenging to detect in many cases. For

viscosities on the order of mPas (similar to water), fluid velocities in LHDAC samples due 447 to buoyancy flow are expected to be $\leq 1 \,\mu m \, s^{-1}$ (Fig. 7). Assuming a minimum detectable 448 flow velocity of $0.01 \,\mu m \, s^{-1}$ (or roughly $0.1 \,\mu m$ per minute) it is evident that in some of the 449 possible parameter space for the LHDAC convective flow will be detectable (Fig. 11). This 450 limit assumes that material would have to move by a significant fraction of the wavelength 451 of visible light (about 1 µm) on a typical experimental timescale (about 1 minute) to be de-452 tected optically, such as by direct visual observations^{3,8,9,19,32,36,37} or by interference changes 453 (i.e. the 'speckle method').^{10,33–35,38–41} Thermal convection should thus be readily visible for 454

FIG. 11. Flow velocity as a function of viscosity and temperature above melting. Blue lines are velocity contours labeled with the logarithmic velocity in $\mu m s^{-1}$, after Eq. (20). Black vertical lines with grey envelopes are the conditions of experiments where peak temperature (1,500-6,000 K) exceeds the melting point by 1, 10, 100, and 1000 K. The red shaded region in the lower right represents the domain where natural convection could be readily observed ($v_{max} > 10^{-2} \mu m s^{-1}$).

455 456

⁴⁵⁷ viscosities similar to water, or lower.

Furthermore, the melting temperature must be exceeded significantly, by 100-1000 K according to our models (Fig. 11), before convection is detectable. Naturally, D and $T_{max} - T_{melt}$ (and hence convective vigor) [Eq. (22)] tend to zero as $T_{max} \rightarrow T_{melt}$, and convection at the melt temperature is not possible regardless of the size of the molten region;

but our results show that considerable overheating is necessary to produce observable flow. 462 This questions the feasibility of reliably detecting melting via convective motion, suggesting 463 that significant overestimates of melting temperature are possible if convective motion is 464 used as a criterion. Indeed, in experiments, initial motion associated with melt may be 465 difficult to see, with 'clear, continuous convection' observed only several hundred degrees K 466 above the putative melting point.^{36,37} However, it should be noted that measurements using 467 *in-situ* motion-based criteria more often underestimate melting temperatures compared to 468 other measurement techniques and theoretical predictions.^{1,4,14–17,42–44} This suggests that 469 the motion observed in many experiments at proposed melting points may not be due to 470 thermal convection, but other causes, as considered in more detail below. 471

The significant overestimation of velocity using order of magnitude dimensional arguments^{21,46} can be explained, in part, by the very confined geometry of melts in the LHDAC, such that the convecting material is at all points being deflected by the boundary of the liquid region rather than freely rising and falling in free space. That the factor *A* decreases with the size of the molten region (Fig. 10B) is further suggestive of this confinement effect.

Another apparent control on peak velocity is that the simulated geometry approaches that 477 of plane-layer convection near the laser heating spot. In perfectly plane-layer (i.e. Rayleigh-478 Bénard) natural convection, with liquid confined in a horizontal layer, perpendicular to 479 gravity, across which a temperature difference is imposed, convection is inhibited for sub-480 critical Ra (i.e. $Ra \leq 10^3$, as characterize the LHDAC). This stability criterion does not 481 generally apply in the LHDAC due to the horizontal thermal gradients.²¹ However, horizontal 482 gradients tend to zero close to the sample hotspot (at r = 0, Figs. 4 and 9), and this evidently 483 inhibits flow in this region. Despite this near-hotspot region having the largest local liquid 484 thickness D and local temperature gradient $|\nabla T|$, peak velocities tend to occur elsewhere, 485 in adjacent areas of the melt (Fig. 4C-E) having smaller D and $|\nabla T|$ (Fig. 4A) but nonzero 486 horizontal temperature gradients $\partial T/\partial r$. This contrasts with expectations from the scaling 487 behavior developed and validated generally in this work that flow velocity should follow a 488 relation similar to 489

490

$$U \propto D^3 |\nabla T|. \tag{23}$$

⁴⁹¹ Consequently the largest flow velocities in the LHDAC occur not at the hotspot, but rather
⁴⁹² around it in a toroidal or ring-like convecting region (see also Fig. 5). This further reflects
⁴⁹³ the strong geometric controls on convective vigor in LHDAC melts.

Buoyant pressure differences across liquid regions that drive natural convection are ex-494 ceedingly small (of order 10^{-2} Pa, Fig. 6B), and so if convective motion is possible, motions 495 driven by other forces of larger magnitude are also possible and, when present, may supersede 496 convection as the dominant mechanism of motion. Non-hydrostatic pressure gradients across 497 solid samples imposed on compression in typical DAC experiments can be of the same order 498 as the static pressure, i.e., $\sim 10^9$ Pa, and could drive sudden, rapid motion as melting occurred. 499 Boundaries in samples (such as planar coupler-medium interfaces) also routinely deform near 500 melting, often into a bead- or droplet-like features^{3,9,32,35,36,44,49} presumably arising from sur-501 face tension; the pressure associated with surface tension is of order $2\gamma/R$ or $\sim 10^3$ Pa for 502 equilibrium interfacial radius of curvature $R \approx 10^{-5}$ m (determined experimentally^{44,49}) and 503 typical surface energy $\gamma \approx 10^{-2} \,\mathrm{N \, m^{-1}}$. Also significant are stresses induced by thermal ex-504 pansion upon heating to the melting point (of order $\beta K_T [T_{melt} - T_{min}]$ or ~10⁹ Pa, for bulk 505 modulus $K_T \approx 10^{10}$ Pa and $T_{melt} \approx 10^3$ K) or by phase transformation, i.e. induced by the 506 melting process itself (of order $K_T \Delta V/V$ or $\sim 10^8$ Pa, for relative volume change $\Delta V/V \approx 1$ 507 % as in high-pressure melting). In addition to the associated forces being significant in the 508 context of driving fluid flow, phase change,^{39,42} surface tensional adjustment, and thermal 509 expansion imply motion directly. Brownian motion has also been proposed as a cause of 510 motion in the LHDAC,¹⁹ though this effect seems limited to cases where mixed phases are 511 present, such as for inhomogeneous or incongruent melting, suspensions or colloids. 512

Most of these phenomena and the associated forces (with the exception of Brownian 513 motion) would be transient in nature, annealing out with time at constant temperature, and 514 so flow and other motion due to them might dissipate as an equilibrium state is reached, 515 and be distinguishable from the continuous motion of thermal convection achieved in the 516 the long-duration limit (the scenario examined in this study). Transient modes of motion 517 reported in experiments,^{36,37,39} such as 'occasional small movements', 'abrupt, discontinuous 518 change', or 'disappearance' of motion, may possibly originate in temporary, annealing driving 519 forces. In the interest of interpreting motion in terms of material viscosity, it is expected 520 that the character of motion depends on and can indicate the primary driving mechanism; 521 observations of flow planform, duration, and temperature-dependence could help isolate the 522 appropriate physical model and thereby enable viscometry. Perhaps most usefully, we find 523 that it is reasonable to interpret persistent motion as being due to convection as it seems 524 difficult to explain this generally through other means. 525

Thermal instabilities that create thermal pressure fluctuations in an already molten sam-526 ple have also been previously proposed as driving continuous flow,^{19,28} however this possibil-527 ity is difficult to substantiate. A thermal perturbation ΔT_i , operating through thermal ex-528 pansion, could drive flow at a velocity comparable to natural convection if $\Delta T_i \approx \Delta P_i / \beta K_T$ 529 where ΔP_i is the buoyant pressure difference across the fluid region in convection, i.e. 530 $\sim 10^{-2}$ Pa (Fig. 6). This implies $\Delta T_i \approx 10^{-7}$ K. Such temperature fluctuations are almost 531 certainly present even under the most stable heating conditions. However, thermal pres-532 sure fluctuations of this type relax very quickly in hydrostatic conditions, on the timescale 533 of pressure wave propagation, $\tau_s \simeq D/v_B$, where v_B the bulk sound velocity – i.e within 534 ~ 1 ns. This is probably not sufficient time to produce detectable flow even if the pressure 535 perturbations, and the associated flow speeds, were substantially larger than for natural 536 convection; moreover, as the thermal response time of the LHDAC is significantly longer 537 than this $(\tau_{\kappa} >> \tau_s)$ it seems unlikely that large-scale thermal pressure perturbations could 538 be imposed within the required timescale. Thus we conclude that differential thermal pres-539 sures are probably not produced in the fluid in nominally continuous heating. A plausible 540 way thermal fluctuations could influence flow would be via the buoyancy force itself. To 541 further examine this issue of instability driven flow, we have tested flow sensitivity to tem-542 perature fluctuations in our simulations by introducing a sinusoidal instability in the laser 543 power and examining its influence on flow (Fig. 12). For μ_w , only fluctuations at a frequency 548 below $\sim 100 \,\mathrm{kHz}$ influence the flow significantly. This is due to the finite response time of 546 the system (Section IIC), on the order of microseconds (τ_{κ}) in this case, such that more 547 rapid fluctuations in laser power are damped and only weakly influence temperature while 548 having no discernible influence on flow. In cases where the flow is influenced, convective 549 flow velocity is only weakly modulated, and thus this phenomenon is not likely to enhance 550 detectability of motion beyond that of steady thermal convection. While thermal fluctu-551 ations are thus unlikely to directly lead to detection of fluid motion, they may indirectly 552 lead to motion via the rapid conductive adjustment of temperature gradients producing, for 553 example, phase changes and melt boundary migration.^{39,42} 554

In any case, the alternative forcings explored above can in principle modify the fluid flow but do not affect the relationship between flow onset and melting. However, on a final note, solids in a high-temperature solid-solid phase transforming,^{10,15,39,51} rapidly recrystallizing,^{4,10,16,17,42,52} or thermally-softened^{14,17,42,43} regime could also play a role in

FIG. 12. Effect of fluctuating laser power (A) on temperature (B) and flow velocity (C) for frequencies ranging from 0.76 to 760 kHz, for μ_w , $T_{melt} = 1000$ K, and $T_{max} = 5051$ K. Above 100 kHz ($\sim 1/\tau_{\kappa}$), the effect of fluctuations on temperature is dramatically reduced and the effect on velocity is negligible and damped by the response time of the system. Variations in fluid dimensions due to temperature change were not considered.

thermally induced motions, and in some cases solid states might respond to the same forces that could affect the fluid states – even, possibly, to the buoyant force. For example, in principle a viscoelastic state¹⁷ could undergo thermal convection; or recrystallization could be induced by the buoyant stresses. Such phenomena could lead to underestimation of melt temperature by motion criteria (cases of $Fe^{3,4}$ and $Ta^{16,35,44}$ have been discussed), however the behavior of solids is beyond the scope of this study.

Accounting for latent heat associated with melting only influences the behavior of the sample when temperatures are unsteady – for example, when temperatures are changing as the simulation is heating up and approaching an equilibrium steady-state (Fig. 3). In the steady-state limit, phase change is not occurring and no energy is used in transforming material, so latent heat does not play a direct role in defining the temperature distribution in the sample, the position of the melt boundary, or the laser power required to sustain the

given temperature. This is consistent with previous conclusions^{27,28} that latent heat alone 571 has little to no effect on the thermal response of the LHDAC, particularly in the steady 572 state limit. Thus our result supports the conclusion that 'plateau'-like deviations from a 573 smooth, continuous increase in temperature with laser power, often seen experimentally near 574 melting and often associated with visible motion,^{3,6,9,19,36,37,41,45} cannot be caused by latent 575 heat and must instead be caused most directly by changes in material physical properties^{27,28} 576 or dynamic phenomena such as rapid convective heat transfer.²⁸ While our study rules out 577 natural convection as a cause of the plateau effect, flow driven by other forces, as discussed 578 above, might play a role if it were particularly vigorous and persistent. 579

580 V. CONCLUSIONS

This study confirms that natural convection is possible in fluids in the laser-heated dia-581 mond anvil cell for a typical experimental configuration, consistent with previous order-of-582 magnitude estimates²¹ and qualitative assessment of experiments.^{3,9,32,34,36–42} Natural con-583 vective motion cannot affect the energy balance of the diamond cell – thermal conduction 584 remains the dominant mechanism of energy transfer in the LHDAC – so the natural convec-585 tion can be thought of as a passive response to temperature gradients. Flow velocities are 586 found to be significantly less than the upper bound expected on the basis of dimensional 587 analysis.^{21,46} We found that the dynamics of natural convection in the LHDAC follow a scal-588 ing law [Eq. (22)] where the Reynolds number (Re) is proportional to the Grashof number 589 (Gr), or Re = AGr, with a constant of proportionality $A \simeq 10^{-3}$. This scaling behavior is 590 expected to be of general validity for the LHDAC when gravity is parallel to the symmetry 591 axis. 592

The routine, wide-ranging observations of motion at high-temperatures in the LHDAC, ^{3,8–10,19,32–41} 593 the observation of 'vigorous' and rapid motion, and the common attribution of this motion 594 to melting and convection, is somewhat in contrast with our conclusion that convective 595 fluid flow would be difficult or impossible to observe in real time when the melting point 596 is just exceeded (Figs 6A and 11). Flow speed increases quadratically with the length 597 scale of the molten region and linearly with the temperature difference across the melt 598 [Eqs (2) and (22)], such that convective flow appears gradually above the melting point, 599 strengthening with increasing peak temperature (and hence melt volume) and becoming 600

realistically detectable only when the melting point is significantly exceeded (by 100-1000) 601 K in representative cases). Thus relating an observation of genuine convective motion to 602 melting is not straightforward, and suggests most directly an upper bound on melt tem-603 perature. Documented motions with different behavior, such as a sudden onset of vigorous 604 motion with increasing temperature, or transient motion at constant temperature, might 605 be driven by other forces (related to sample annealing), and could occur at or nearer to 606 precise melting points, and potentially below them (as for fast recrystallization^{4,10,16,17,42,52}). 607 Indeed, non-convective motions could dominate in a number of scenarios. There is thus 608 a need to identify the dominant causes of flow and motion in the LHDAC and hence the 609 relationship of these motions to melt temperatures and melt properties. Continuous, steady 610 fluid motion is likely an indication that convection is occurring, providing a simple initial 611 test of whether the observed process of motion is plausibly convective in nature. Our study 612 predicts specific observables, such as convection in a ring or torus for axially oriented gravity, 613 annealing-driven flow, and temperature-dependence of flow vigor, that can better inform 614 the true nature of flow phenomena, and their origin in convection or otherwise. 615

Another common criterion for high-pressure melting are anomalies (such as plateaus) 616 in temperature observed when increasing laser power through melting points.^{3,6,9,19,36,37,41,45} 617 Our models rule out both latent heat of melting and fluid flow as potential causes for 618 these anomalies, assuming well-annealed samples at thermal equilibrium. This restricts the 619 possible origin of such plateaus, with the most probable remaining general explanation being 620 changes in material properties upon melting (e.g. thermal conductivity, heat capacity, or 621 optical properties). Studies of motion and temperature as a function of both laser power 622 and time since power increase could yield valuable information about the nature of motion, 623 its principal causes, and its relationship to melting and other common melting criteria. 624

It is interesting to note that, as demonstrated in our simulations, pressure gradients can never be fully annealed in the LHDAC as buoyant pressure differences always exist. Whether the liquid (or solid) responds to these buoyancy forces on an experimental timescale is dependent on the material properties. Buoyant forces should become increasingly important at high temperatures where material softening, melting, recrystallization and other forms of annealing are increasingly available to relax shear stresses.

The measurement of fluid transport properties at conditions of extreme pressure and temperature is a longstanding challenge. Due to the strong control of flow speed by viscosity

in LHDAC convection, there are good prospects for determining viscosity at high pressure 633 using the melt production and flow behavior induced by laser heating. If the origin of 634 flow is natural convection, the flow velocity is inversely proportional to viscosity [Eq. (22)]. 635 Since viscosity varies by roughly 10 orders of magnitude over the typical viscosity range 636 of natural fluids, the relatively minor uncertainties in the other parameters appearing in 637 the scaling model [Eq. (22)] (e.g. melt size, melt temperature, and peak temperature) do 638 not have a major influence on determining, at least, the order of magnitude of viscosity. If 639 melt dimensions could be assessed precisely, for example by direct observation as part of 640 fluid velocity measurements, the quality of the viscometry could be particularly accurate. 641 Recent efforts to quantify motion via the changing speckle pattern of laser light reflected 642 from molten samples suggests one way to assess the vigor and rate of flow,⁴¹ however a 643 physical understanding of the relationship between speckle changes and flow rates must 644 be established. In any case, more direct probes of flow rates, streamlines, and spatial 645 distributions may be required to provide a complete comparison to models and suitable 646 data for accurate viscometry. 647

Observation of convective motion alone can be enough to place a significant constraint 648 on viscosity. Only convective flow in fluids with viscosities similar to water ($\sim 10^{-3}$ Pa s), or 649 lower, are readily detectable in the LHDAC according to our simulations (Fig. 11). Mean-650 while, condensed fluids rarely exhibit viscosities much lower than 10^{-4} Pas (group 1 and 651 low-Z group 18 elements being notable exceptions). Thus it is likely that, in most cases, 652 detectable convection corresponds to a viscosity within about an order of magnitude of that 653 of water. For example, the routine observation of apparent convective motion in molten Fe 654 under pressure^{3,8,9,36} is consistent with the common assumption that molten Fe at Earth's 655 core conditions has a viscosity similar to water.^{2,53} This also suggests that melt detection by 656 sample convective motion should not be possible for viscous melts such as silicate liquids. 657

In summary, the intrinsic natural convection in melts produced by laser heating in the diamond anvil cell may be one way of measuring fluid viscosities at extreme pressure and temperature. In addition to providing essential data on fluid transport under pressure, as relevant to melts in planetary deep interiors, high-pressure viscosity measurements offer one way to characterize pressure-induced changes in fluid bonding and structure that may be otherwise difficult to detect, such as liquid-liquid phase transformation, polymerization or dissociation. Our results suggest a novel approach to measuring viscosity in the laser-heated

diamond cell, by comparing observations of convective flow speeds in melts with numerical 665 models. Such models are essential for describing this unique case of convection at ultra-low 666 Rayleigh number, in which geometric controls on flow are especially pronounced. Theoreti-667 cal, *ab-initio* descriptions of materials transport and mechanical properties at extremes can 668 also assist in the collection and interpretation of motion data. Of particular interest for the-669 oretical investigation are the viscosities of high pressure liquids, but mechanical properties 670 of high pressure-temperature solids are also needed, for example, where melt temperatures 671 approach bond-dissociation and diffusion-activation energies⁵ and where viscoelastic¹⁷ or 672 rapidly-recrystallizing^{4,10,16,17,42,52} states appear. 673
