To be submitted to Electrochemistry Communications
Abstract

Triphasic microporous materials (containing solid, liquid, and gas) are of interest in electrocatalysis. In this exploratory study, a polymer of intrinsic microporosity (PIM-EA-TB) is impregnated with PdCl$_4^{2-}$ metal precursor and vacuum-carbonised to give an electrically conductive microporous heterocarbon with embedded Pd nanoparticles of typically 10 - 30 nm diameter. This microporous composite catalyst is formed (via spin-coating) as “flakes” of typically 100 nm thickness and 1 to 20 µm diameter that are readily re-deposited onto glassy carbon electrode substrates. Due to triphasic conditions, Pd@cPIM electrocatalytic reactivity is high, but only for gases (H$_2$ oxidation or O$_2$ reduction). This selectivity is observed even in the presence of excess formic acid fuel in the aqueous/liquid phase. Potential for application in membrane-less micro-fuel cells is discussed.

Keywords: gas binding; triple phase reaction zone; fuel cell; CO$_2$ reduction; microporosity.

1. Introduction

Multi-phasic systems are crucial in electrocatalysis where poorly soluble gases such as hydrogen, oxygen, carbon dioxide, or ammonia need to effectively interact with nano-catalysts in three dimensional catalyst architectures [1,2]. Enhancing reactivity is possible by increasing pressure or by employing triple-phase boundary gas | liquid | solid reactions conditions [3]. Enhancing reactivity in the triple phase boundary reaction zone is linked to microporosity, surface energy, and catalyst design.
Recently, novel materials have emerged with “triphasic” characteristics in metal-organic frameworks [4], clays [5], zeolites [6], and in porous carbons [7]. Perhaps surprisingly, the presence of the liquid sometimes serves to enhance the gas binding ability of the microporous material [8]. For an electrically conductive microporous carbon material with both gas and liquid electrolyte permeating through the pores, it can be proposed that diffusion of gases is affected beneficially (via gas inclusions) and diffusion of aqueous solutes is affected detrimentally (blocked by gas inclusions).

Polymers of intrinsic microporosity (PIMs) [9] are comprised of a continuous rigid network of inter-connected micropores, typically less than 2 nm in size. Due to the high structural rigidity of the polymer backbone, efficient packing is hindered and consequently, PIMs possess a large number of void spaces for liquid and gas to permeate. Additionally, PIMs (such as PIM-EA-TB, prepared from a diaminobenzothiazole “EA” monomer via a Tröger base “TB” coupling [10], see structure in Figure 1) are readily soluble in organic solvents (chloroform) and can be easily processed to give coatings and deposits. These highly microporous materials are predominantly being developed for membrane gas separations [11], but have also attracted attention for heterogeneous electrocatalysis [12].

In this study, the polymer PIM-EA-TB is converted into a microporous heterocarbon under mild carbonisation conditions at 500 °C. It was recently demonstrated that during vacuum-carbonisation of PIM-EA-TB a decrease in surface area occurs (the Brunauer-Emmett-Teller or BET surface area changed from 1027 m²g⁻¹ to 242 m²g⁻¹) but microporosity increases [13]. In related studies, a nano-particulate heterocarbon material with slow ingress of aqueous electrolyte and with pH-dependent capacitance was obtained [14] and nano-platinum was
formed embedded in the microporous heterocarbon [15]. Here, nano-palladium is embedded into carbonised PIM-EA-TB (or Pd@cPIM). There are previous reports on the formation and application in catalysis of nano-palladium embedded in heterocarbon host materials [16,17]. In this study, the nano-composite is prepared via one-step vacuum-carbonisation and tested for electrocatalytic properties.

2. Experimental

2.1. Materials and Reagents. Chemicals were purchased from Sigma-Aldrich and used without purification. PIM-EA-TB was obtained following a literature procedure [10]. Laboratory grade hydrogen gas, oxygen gas, and argon gas were obtained from BOC, UK. Solutions were prepared using deionised water (with resistivity of 18.2 MΩ cm at 22 °C).

2.2. Catalyst Preparation Conditions. PIM-EA-TB was dissolved in chloroform (4 weight %). Thin polymer films were prepared on glass microscopy cover slips by spin coating at a rotation speed of 1000 rpm for 1 minute (WS-650Mz-23NPP, Laurell Technologies), followed by immersion in PdCl$_4^{2-}$ precursor solution (10 mM PdCl$_2$ in 0.1 M HCl) for 5 minutes, and then rinsing and drying under ambient conditions to give orange-yellow films. Vacuum carbonisation was performed for samples wrapped in aluminium foil under oil pump vacuum (ca. 0.2 mbar) in a quartz tube at 500 °C for 3 h.

2.3. Electrode Preparation. Vacuum-carbonised samples (Pd@cPIM or cPIM, estimated 200-300 µg per sample) were stripped from the glass cover slips by sonication/scraping of flakes into 1.5 cm$^3$ isopropanol to form a suspension. Volumes of 12 µL (estimated 0.2 mg cm$^{-3}$) were drop-casted onto glassy carbon (GC) electrodes and dried to yield modified surfaces with
approximately of 1.6 – 2.4 µg of the material of interest. Electrochemical measurements were performed at room temperature with Ivium Compactstat (Ivium, Netherlands) in a three-electrode cell with KCl-saturated reference electrode, GC working electrode (BAS, 3 mm diameter), and Pt wire counter electrode. In some experiments a palladium foil 3 × 3 mm² on a glass support served as the working electrode.

3. Results and Discussion

3.1. Characterisation of Pd@cPIM. Figures 1A and 1B show TEM data for Pd@cPIM and cPIM which clearly reveal palladium inclusions. The electron diffraction pattern in Figure 1C confirms the presence of Pd nanoparticles [18], which are typically 10 to 30 nm in diameter. SEM data suggest typical flake sizes of 1-20 µm with a thickness of about 0.1 µm (Figure 1D). As seen from the Raman data in Figure 1E, the main peak at 1354 cm⁻¹ can be assigned to the D-peak of disordered amorphous carbon, while the 1598 cm⁻¹ peak is attributed to the G-peak of graphitic carbon [19]. Consistent with previous work, further deconvolution of the Raman spectra gives a shoulder peak corresponding to the TPA-band as well as the A band. [14]
3.2. Hydrogen Oxidation. The electrocatalytic oxidation of H\textsubscript{2} (1 atm, in 0.1 M HClO\textsubscript{4} electrolyte at a scan rate of 10 mV s\textsuperscript{-1}) is initially employed to characterise the reactivity of Pd@cPIM. Figure 2A shows absence of catalysis on bare GC but presence of H\textsubscript{2} oxidation (ca. 40 µA cm\textsuperscript{-2}) on both bare Pd and Pd@cPIM. The high capacitive background current for Pd@cPIM is consistent with values reported for similar materials [14], but the lack of observable Pd surface redox processes for Pd@cPIM suggests that a dense micro-porous heterocarbon has been formed when compared to recently reported Pt@cPIM materials [15].
Figure 2. (A) Cyclic voltammograms (scan rate 10 mV s\(^{-1}\)) for a GC electrode, bare Pd, and Pd@cPIM-modified GC immersed in hydrogen-saturated 0.1 M HClO\(_4\). (B, D) Cyclic voltammograms (scan rate 1 mV s\(^{-1}\)) for a bare Pd and a Pd@cPIM-modified GC immersed in 1.0 M HCOOH under argon or oxygen saturated conditions. (C, E) Cyclic voltammograms (scan rate 1 mV s\(^{-1}\)) for a bare Pd and a Pd@cPIM-modified GC in oxygen-saturated HCOOH of varying concentrations at (i) 0.1 M, (ii) 0.5 M, (iii) 1.0 M and (iv) 5.0 M.
3.3. Oxygen Reduction in the Presence of Formic Acid. As observed from Figure 2B, on bare Pd, oxidation at -0.2 V vs. SCE is consistent with formic acid decomposition to adsorbed hydrogen and CO₂ [20,21]. The presence of oxygen reduction is revealed by its onset at +0.3 V vs. SCE. The effect of varying formic acid concentration is shown (Figure 2C). Thus, on a bare Pd catalyst, two competing processes (oxygen reduction and formic acid oxidation) occur simultaneously. For Pd@cPIM (Figures 2D, E), the onset of oxygen reduction occurs again at approximately +0.3 V vs. SCE. No significant formic acid oxidation peak is recorded, suggesting that while Pd@cPIM is electrocatalytically reactive, activity is only limited to oxygen reduction. At high formic acid concentrations (5.0 M), the shape of the CV begins to change and formic acid oxidation seems likely but only at potentials positive of 0.3 V vs. SCE.

Next, a two-electrode system was investigated with both bare Pd and Pd@cPIM electrodes immersed in aqueous 1.0 M or 5.0 M formic acid (Figure 3A). The open circuit voltage is approximately 0.28 V for 1.0 M formic acid (and slightly less for 5.0 M formic acid). This is due to a negative potential at the bare Pd electrode (where formic acid oxidation dominates) and a positive potential at the Pd@cPIM electrode (where oxygen reduction dominates). A voltage scan shows power generation in the potential range from 0.28 V to lower potentials. However, the curves do not retrace when scanning the potential back positive; some catalytic efficiency is lost in the high current region. The power plot (Figure 3B) shows a maximum power at approximately 0.15 V. Doubling the amount of Pd@cPIM catalyst can increase both voltage and power (Figure 3C). A power of 5 µW cm⁻² is reasonable when compared to similar membrane-less micro-fuel cell systems [22] and limited here mainly by the kinetically slow oxygen reduction reaction. There are previous reports of membrane-less formic acid fuel cells being operated at higher temperatures and achieving higher power density with flow [21]. In order to improve the stationary micro-power generator, more catalyst could be applied. The
reaction of oxygen on bare Pd also needs to be suppressed (e.g. by reactor design exploiting the microporosity of Pd@cPIM in a gas diffusion electrode and keeping bare Pd as internal electrode).

Figure 3. (A) Two-electrode voltammetry (scan rate 1 mV s\(^{-1}\)) for bare Pd (anode) and Pd@cPIM (cathode) immersed in (i) 1.0 M and (ii) 5.0 M HCOOH (inset showing the parameters \(E_{\text{cathode}} - E_{\text{anode}}\), \(I_{\text{anode}}\), and \(I_{\text{cathode}}\) in voltammetry data). (B) Power (= current \(\times\) voltage) plotted versus voltage. (C) Power plotted for the two-electrode experiment in 1.0 M formic acid with (i) one deposition and (ii) two depositions of Pd@cPIM.
4. Conclusions

It has been shown that selectivity for gas phase reactions (hydrogen oxidation and oxygen reduction) can be achieved when embedding nano-Pd catalysts into a microporous heterocarbon host. Triphasic conditions are caused by the chemical nature of the PIM precursor material. There are many potential applications where effective and selective gas phase reactions are important including hydrogen, ammonia and methane fuel cells. Catalyst selectivity is also crucial for membrane-less micro-power generator applications.
