#### 26 Abstract

47

Computed tomography (CT) parameters, including spiral computed tomography scanning 27 (SCTS) parameters, intramuscular fat (IMF) and mechanically measured shear force were 28 29 derived from two previously published studies. Purebred Texel (n = 377) of both sexes, females (n = 206) and intact males (n = 171) were used to investigate the prediction of IMF 30 and shear force in the loin. Two and three dimensional CT density information was available. 31 Accuracies in the prediction of shear force and IMF ranged from  $R^2 0.02$  to  $R^2 0.13$  and  $R^2$ 32 0.51 to R<sup>2</sup> 0.71 respectively, using combinations of SCTS and CT scan information. The 33 34 prediction of mechanical shear force could not be achieved at an acceptable level of accuracy employing SCTS information. However, the prediction of IMF in the loin employing 35 information from SCTS and additional information from standard CT scans was successful, 36 37 providing evidence that the prediction of IMF and related meat eating quality (MEQ) traits for Texel lambs in vivo can be achieved. 38 39 40 **Keywords:** spiral x-ray computed tomography, lamb, meat quality, intramuscular fat. 41 **1. Introduction** 42 Computed tomography (CT) is a non-invasive, diagnostic tool initially developed for use in 43 human medicine to improve the imaging of soft tissue structures and assist in diagnosing 44 45 conditions or diseases not directly associated with bone structure. Over the last few decades CT has been adopted for use in animal breeding and is now routinely used in selective 46

animals. More recently, the prediction of aspects of meat quality (MQ) such as intramuscular
fat levels (IMF), fatty acid profiles and tissue composition have been investigated both *in*

breeding programs for sheep in the UK to accurately estimate carcass composition of live

50 vivo and post mortem in meat producing species (Font-i-Furnols, Brun, Tous, & Gispert,

51 2013; Kongsro & Gjerlaug-enger, 2013; L. Bünger, J.M. Macfarlane, N. R. Lambe, J.

Conington, K. A. McLean, K. Moore, 2011; Prieto et al., 2010). The basic principle of CT is 52 the measurement of the spatial distribution of any physical quantity. Offering greater contrast 53 54 in the imaging of soft tissue to that seen in conventional radiography (Kalender, 2006). The first method of image capture most commonly used is 'single-slice' scanning. During single-55 slice scanning, x-rays are used to generate cross-sectional, two-dimensional images of the 56 selected region of a subject. Each image is produced by rotation of the x-ray tube 360° around 57 the subject. Attenuation of radiation through the tissues can then be measured, with 58 59 differences indicating different tissue densities.

60

Advances in scanning technology have resulted in the development of contiguous scanning 61 62 procedures such as spiral CT scanning (SCTS), capable of producing a series of images in a single contiguous scan at intervals of as little as 0.6 mm apart. The advantage is that multiple 63 images can be acquired faster, at reduced intervals, resulting in increased information 64 65 acquisitions in less time. Recent studies provide evidence that muscle density information from single or multiple CT scans in sheep, can provide moderately accurate predictions of 66 IMF content *in vivo*. Prediction accuracies range from  $R^2 = 0.33$  to 0.68 using several 67 approaches including various CT parameters (Clelland et al., 2014; Karamichou, Richardson, 68 Nute, McLean, & Bishop, 2006; Lambe et al., 2008; Lambe, McLean, et al., 2010; J. M. 69 70 Macfarlane, 2006). The aim of this study was to investigate any gains in the prediction of IMF content and shear force in the loins of Texel sheep that may be achieved by utilizing the 71 wealth of information that relatively new SCTS techniques may provide. 72

73

74

#### 76 **2. Materials and Methods**

#### 77 2.1. Experimental animals

The CT parameters, including SCTS parameters, IMF and shear force in the loin were 78 79 derived from two previously-published studies. The first of these studies (Exp. 1), was conducted over two years (2003 to 2004) and investigated the use of various in vivo 80 81 measurement techniques (ultrasonography, video image analysis and CT), to predict carcass and meat quality in purebred Texel (n = 240) and Scottish Blackface (n = 233) lambs. The 82 full study and methods are detailed in Lambe et al. (2008). The second study (Exp. 2) was 83 84 conducted in 2009 and investigated the genotypic effects of the Texel muscling quantitative trait loci (TMQTL) on carcass and meat quality in purebred Texel lambs (n = 137). Full 85 details are published in Lambe et al. (2010). The combination of these data from Exp. 1 and 86 87 Exp. 2 comprised data from pure-bred Texel lambs (n = 377) of both sexes, females (n = 206) and intact males (n = 171). Lambs were reared to weaning as either singles (n = 184), twins 88 (n = 168) or artificially hand reared (n = 25). Mean age at CT was 132 d (SD 21.1, range 91-89 90 202 d); with mean live weight 35.3kg (SD 4.9, range 20-49kg). Lambs were CT scanned preslaughter using a Siemens Somatom Esprit scanner. All lambs were lightly sedated 91 (Rompun<sup>®</sup>, Bayer animal health, Bayer plc., Newbury, UK) at a dose of 0.1-0.2mg xylazine 92 hydrochloride/kg body weight, then secured in a purpose-built cradle before being CT-93 scanned. 94

95

96

### 2.2. Single-slice and spiral x-ray CT measurements and image analysis

A series of spiral CT images at intervals of 8mm were selected from the loin region of each
lamb. The first image was taken where the transverse process of the 7<sup>th</sup> lumbar vertebra
appears and the last image in the series where the transverse process of the 1<sup>st</sup> lumbar
vertebra is no longer visible (Fig.1a). Two-dimensional cross-sectional single-slice scans

were also used, taken at two defined anatomical positions, through the top of the leg at the
ischium bone (ISC), and through the chest at the 8<sup>th</sup> thoracic vertebra (TV8), details of the
images used and the location are presented in Fig.1b.

104

#### 105 Insert Figure 1 Here

106

This two dimensional method of scanning at these particular anatomical sites (including an 107 additional scan at the 5<sup>th</sup> lumbar vertebra, which was not used in this study), is currently used 108 in UK terminal sire breeding programs to provide accurate predictions of fat and muscle 109 weights in the carcass. This method, defined as 'reference' scanning (L. Bünger, J.M. 110 111 Macfarlane, N. R. Lambe, J. Conington, K. A. McLean, K. Moore, 2011), optimizes the 112 number of images required to be taken across the body of the sheep while maximizing the accuracy of estimations for carcass traits. Images were produced with a resolution of 512 x 113 512 pixels with a 450mm field of view, producing images with a pixel size of  $0.77 \text{mm}^2$  in 114 two dimensions. Spiral images were produced at the same resolution and field of view at 115 intervals of 8mm, producing images with a voxel size of 6.2mm<sup>3</sup>. 116 Automated analyses were performed on the images produced, to separate carcass from non-117 carcass tissues (Glasbey & Young, 2002), and calculate the density of each pixel in 118 Hounsfield units (HU), the standard quantitative scale for describing radiodensity. In the final 119 120 segmented image each pixel was allocated to fat, muscle or bone using image thresholding techniques (Mann, Young, Glasbey, & McLean, 2003). The thresholds in Hounsfield units 121 (HU) defined for the CT scanner (Siemens Somatom Esprit single slice) were Fat = -174 to -122 12HU, Muscle = -10 to 92HU and Bone = 94HU and above, based on previous calibration 123 trials. Areas (mm<sup>2</sup>) and average densities (HU) of muscle and fat in each two dimensional 124 image were calculated, as well as standard deviations of the density values allocated to each 125

126 tissue. Combining all pixels allocated as either fat or muscle enabled the use of a novel average 'soft tissue density' and standard deviation. The SCTS images were used to calculate 127 weighted average densities of muscle, fat and soft tissue (average tissue density, in each 128 129 individual scan image, weighted for tissue area in that image and averaged across all images in the spiral scan series). Volumes of each tissue (mm<sup>3</sup>) were also calculated. The resulting 130 SCTS parameters included; weighted muscle and fat densities and relating standard 131 deviations, weighted soft tissue densities and standard deviation, and calculated muscle and 132 fat volumes (mm<sup>3</sup>). The CT parameters measured from the two dimensional reference scans 133 134 in the ISC and TV8 regions were muscle density, fat density and related standard deviations, as well as the soft tissue densities and standard deviations of soft tissue densities. Muscle area 135 and fat area tissue measurements (mm<sup>2</sup>) were also calculated for each of the reference scan 136 137 images. Total CT predicted carcass fat (PrCfat), as a measure of subcutaneous and intermuscular fat in the entire carcass, was also predicted using a breed-specific prediction 138 equation developed from previous research (Macfarlane et al., 2006): 139  $PrCfat(kg) = (-2236 + (LW \times 80.26) + (ISCFA \times 0.21) + (LV5FA \times 0.19) + (ISCFA \times 0.21) + (LV5FA \times 0.19) + (ISCFA \times 0.21) + ($ 140  $(TV8FA \times 0.221))/1000$ 141 Where PrCfat is the CT predicted weight of subcutaneous and intermuscular fat (kg), LW is 142 live weight at CT scanning, ISCFA is the area of pixels allocated as fat in the scan image 143 taken at the ischium (mm<sup>2</sup>), LV5FA is the area of pixels allocated as fat in the scan image 144 taken at the 5<sup>th</sup> lumbar vertebra (mm<sup>2</sup>) and TV8FA is the area of pixels allocated as fat in the 145 scan image taken at the 8<sup>th</sup> thoracic vertebra. Details, acronyms and descriptions of each CT 146

148

147

and MQ trait are presented in Table1.

149

151 2.3. Slaughter procedure and meat quality parameter measurements

The loin muscle (*M. longissimus lumborum*) was removed from the right side of each carcass 152 included in Exp. 1, vacuum-packed aged for 7 days, and frozen prior to meat quality analysis 153 154 at the University of Bristol. Carcasses included in Exp. 2 were subjected to high voltage electrical stimulation (700 volts RMS for 45 seconds applied between the end of the 155 processing line and the chiller), chilled and aged for between 7-9 d and dissected, removing 156 157 the loin muscle (*M. longissimus lumborum*) from the right side of the carcass. In both Exp. 1 and 2, IMF content was measured in a cross-sectional slice taken from the cranial end of the 158 159 muscle at the first lumbar vertebra. Each sample was blended to a fine paste and IMF content was measured using petroleum ether (B.P. 40-60°C) as the solvent in a modified Soxhlet 160 extraction (AOAC, 1990). Mean IMF was 1.48% (SD 0.68) and ranged from 0.27 – 3.88%. 161 162 The majority of lambs were slaughtered 4-8 d after CT scanning (n=217), and the remaining lambs were slaughtered 32-33 d after CT scanning (n=160), to allow for a 30 day withdrawal 163 period from the CT sedative and subsequent taste panel analysis (which formed part of a 164 wider study). Shear force was also measured, using a TA-XT2 texture analyzer (Stable Micro 165 System, Surrey, UK) fitted with Volodkevich-type jaws, a standard compression method to 166 determine tenderness simulating the action of the incisor tooth (Volodkevich, 1938). Loins 167 were cooked 'sous-vide' (in vacuum pack bags) in a water bath at 80°C to an internal core 168 169 temperature of 78°C (Teye et al., 2006) monitoring individual loin temperature using a digital 170 temperature probe (Hanna Instruments UK, Eden Way, Bedfordshire) . Samples were then immediately cooled in iced water and held at 4°C overnight for a minimum period of 12 171 hours. Ten 10 x 10 x 20mm samples were cut from each loin following the direction of the 172 173 muscle fibers and sheared at a constant speed of 1mm/s perpendicular to the muscle fiber direction. Shear force was recorded as the force required (kgF) to compress the sample, with 174

175	greater values for less tender samples. Results were averaged over the ten samples taken from
176	each loin. Mean shear force was 3.4kgF (SD 1.56) and ranged from 1.39 – 10.72kgF.

#### *2.4. Statistical analysis*

Lambs with no IMF data were removed (n = 2), lambs without full CT information were removed (n = 2), and finally lambs with IMF content greater than three standard deviations from the mean were identified as outliers and also removed (n = 3). Initial regression analysis and subsequent model checking (Distribution of residuals) suggested the need for transformation of shear force data. As a result shear force was log-transformed and fitted to a normal distribution prior to any regression analysis. The number of days from CT scanning to slaughter (group 1: 4-8 d; group 2: 32-33 d, accounting for lambs subjected to a withdrawal period to allow subsequent taste panel analysis) was tested using a general analysis of variance in Genstat14<sup>TM</sup> adjusted for PrCfat, and provided evidence of no significant effect on IMF content (P = 0.80) or shear force (P = 0.07). The term was also fitted as an independent variable in the simple regression models in order to test the relationship between days to slaughter and the CT parameters and was again not significant when tested on IMF (P = 0.71) and shear force (P = 0.19) therefore was not included in the analysis. A summary of the CT traits tested in the models are presented in Table 1. Histograms of MQ traits (shear force prior to transformation and IMF) are presented in Fig. 2. 

**Table 1:** Acronyms and summary statistics of both CT and meat quality traits along with trait
 descriptions, means and standard deviations (SD) in the Texel data utilized in the prediction TIMF (n = 370)

207	Sixteen models were tested in the analyses (Table 2), termed models A-P using information
208	from SCTS only ( <sup>sp</sup> ) and a combination of SCTS and reference information ( <sup>com</sup> ). Models
209	with one or two variables included in the maximum model were analyzed using simple and
210	multiple linear regression, respectively, whilst models employing CT data with more than
211	two variables were analyzed using stepwise linear regression in Genstat14 <sup>TM</sup> (Payne, Murray,
212	Harding, Baird, & Soutar, 2011), to optimize the number and combination of independent
213	variables from the maximum fitted model. Models were then tested for significant differences
214	between correlation coefficients ( $\sqrt{Adj} R^2$ ) applying standard methods using Fisher's Z
215	transformation (Mudholkar, 2006). Final models were identified as those with significantly
216	greater prediction accuracies of MQ traits than the baseline model (Model A). These models
217	were then validated. During validation, available data were split using a natural time series
218	separation in the data, as described by Snee (1977). Experiment one data was employed as a
219	calibration data set, and experiment two data as a validation data set. Summary statistics for
220	MQ traits and CT measured traits for both calibration and validation data sets are presented in
221	Table 3, Histograms of MQ traits (shear force prior to transformation and IMF) are presented
222	in Fig. 3.

<sup>236</sup> 

The fitted terms identified in the most accurate prediction models derived from the regression analyses using the entire data set were used to produce prediction equations using the calibration data set (Exp. 1). These equations were then used to predict MQ traits of the lambs included in the independent validation data set (Exp. 2). The coefficient of determination (R<sup>2</sup>) and residual mean square error of prediction (RMSEP) were calculated for the predicted MQ traits against chemically extracted IMF and mechanical shear force, to identify the simplest and most reliable single predictive model or group of predictive models.

#### 252 **3. Results**

253 3.1. Predicting shear force and IMF content using SCTS information

Very little of the variation in shear force was accounted for by PrCfat (Adj  $R^2 = 0.05$ ),

however PrCfat accounted for a moderate amount of the variation in IMF (Adj  $R^2 = 0.50$ ).

256 Compared to the baseline (Model A; Table 2), using only information from CT derived

257 predicted carcass fat, seven models that included additional CT variables, from the fifteen

258 models tested, were identified as being statistically significantly more accurate in the

prediction of IMF (P > 0.05). None of the additive models using only spiral CT information

were significantly more accurate (P < 0.05) in prediction of shear force when compared to the

261 baseline (Table 4).

262

From the seven models identified with significantly increased prediction ability of IMF when compared to Model A, using only SCTS information, the model with the greatest accuracy was identified as model L (Adj  $R^2 = 0.70$ ). This model included CT predicted carcass fat (PrCfat), weighted muscle density (w\_md), fat volume and muscle volume (f\_vol, m\_vol), resulting in the prediction equation:

269 0.000000338 ×  $m_vol''$ 

The six remaining models including only SCTS information identified as better predictors of IMF than PrCfat alone were compared with the maximum benchmark (Model L). Models with significantly reduced accuracy (P > 0.05) compared to the benchmark model L were discarded. This included model P (Table 4), which left a total of six models with correlation coefficients that were not significantly different, essentially meaning that the prediction ability of these six models is statistically similar, thus identifying a group of models that would predict IMF equally using SCTS information. Model K was also dropped as it was entirely the same final model as model J following stepwise linear regression. The final selected models included; model B (Adj  $R^2 = 0.67$ ), model F (Adj  $R^2 = 0.68$ ), model H (Adj  $R^2 = 0.67$ ), model J (Adj  $R^2 = 0.69$ ) and model L (Adj  $R^2 = 0.70$ ).

280

3.2. Predicting shear force and IMF content using a combination of SCTS and reference scan
information

Models using both SCTS information (<sup>sp</sup>) and a combination of SCTS information and reference information (<sup>com</sup>) were again compared to the simple linear model using only PrCfat for the predictions of both shear force and IMF. In the analysis for the prediction of shear force, prediction accuracies were significantly improved with the inclusion of information from the reference scan images (ISC, TV8). Nonetheless, the overall results show that the maximum prediction accuracy achieved for shear force, from models developed was Adj R<sup>2</sup> = 0.13 (Table 4).

290

In the prediction of IMF ten of the fifteen models tested were significantly greater in prediction accuracies than that of PrCfat alone (P < 0.05). From these models the single 'best' model was identified as model  $L^{com}$  (Adj  $R^2 = 0.71$ ) and used as a maximum benchmark model:

296  $0.000001196 \times f_vol + 0.0168 \times ISCMD + 0.0371 \times ISCMSD - 0.0000393 \times ISCMA - 0.00000393 \times ISCMA - 0.0000393 \times ISCMA - 0.00000393 \times ISCMA - 0.0000393 \times ISCMA - 0.0000393 \times ISCMA - 0.0000393 \times ISCMA - 0$ 

297  $0.0543 \times TV8MD + 0.0000236 \times TV8MA - 0.0001298 \times TV8FA$ "

298 Where PrCfat is CT predicted carcass fat, w\_md is weighted muscle density in the spiral

information, m\_vol is the volume of muscle estimated from the spiral information, f\_vol is

the volume of fat estimated from spiral information, ISCMD is the average muscle density in

the ischium scan region, ISCMSD is the standard deviation of muscle density in the ischium

302 scan region, ISCMA is the estimated area of muscle in the ischium scan region, TV8MD is the average density of muscle within the 8<sup>th</sup> thoracic vertebra region, TV8MA is the 303 estimated muscle area within the 8<sup>th</sup> thoracic vertebra region and TV8FA is the estimated fat 304 area within the 8<sup>th</sup> thoracic vertebra region. 305 All models were then tested against the benchmark and any that were statistically 306 significantly different in prediction accuracy were discarded (P > 0.05), which included 307 Model  $M^{com}$  (Adj  $R^2 = 0.63$ ). These analyses therefore identified nine "best" models with 308 similar prediction abilities:  $L^{com}$  (benchmark; Adj  $R^2 = 0.71$ );  $F^{com}$ ,  $J^{com}$  and  $K^{com}$  (Adj  $R^2 =$ 309 0.70);  $B^{com}$  and  $H^{com}$  (Adj  $R^2 = 0.68$ );  $O^{com}$  and  $P^{com}$  (Adj  $R^2 = 0.67$ ); and  $N^{com}$  (Adj  $R^2 = 0.67$ ); 310

311 0.66). Regression results for all models are presented in Table 4.

**Table 4:** Regression results for the prediction of ShF or IMF, presented is the adjusted coefficient of determination (Adj  $R^2$ ) and residual mean square error (RMSE) using information from SCTS only (sp) or a combination of SCTS and two-dimensional reference scans (com), using the whole dataset (n=370).

316 <sup>sp</sup> Using SCTS information

317 <sup>com</sup> Using a combination of SCTS and reference CT information

<sup>\*</sup>Adj R<sup>2</sup> differs significantly from the baseline model (A) (P > 0.05)

319 <sup>\*\*</sup>Adj R<sup>2</sup> does not differ significantly from the maximum benchmark model (P < 0.05)

# *3.3. Model Validation and selection*

321	Given the poor prediction abilities of CT for shear force ( $R^2 < 0.30$ ) using the parameters
322	tested, validation analysis for the prediction of shear force was not carried out. Fourteen
323	possible models in the prediction of IMF were identified. None of these models had
324	significantly less prediction accuracy (P < $0.05$ ) than the single 'best' model from both SCTS
325	information and a combination of SCTS information and reference information (Model L <sup>com</sup> ),
326	so all were retained for validation analyses, with Adj $R^2$ ranging from 0.67 to 0.71. For
327	validation, fourteen prediction equations were derived using the calibration data set ( $n = 236$ ),
328	corresponding to the independent variables identified in the final selected models from the
329	primary stepwise regression analysis. The models were then used to predict the chemical IMF
330	values of lambs included in the independent validation data set ( $n = 134$ ). Final validation
331	results, coefficients of determination $(R^2)$ and residual mean square errors of prediction
332	(RMSEP) are presented in Table 5.

347 square error of prediction (RMSEP) of the validation data

346

<sup>sp</sup> Model uses information from spiral scans only

<sup>com</sup> Model uses information from a combination of spiral and two dimensional scans
 350

351 The model with the strongest validity was model  $N^{com}$  ( $R^2 = 0.67$ , RMSEP = 0.31)

using both SCTS information and reference scan information, including CT predicted carcass

fat (PrCfat), weighted density of soft tissue and its standard deviation (w\_std and w\_stsd) in

the spiral scan of the loin, soft tissue density and its standard deviation in the ischium scan

355 (ISCSTD and ISCSTSD), soft tissue density in the 8<sup>th</sup> thoracic vertebra scan and its standard

deviation (TV8STD and TV8STSD). This model ( $N^{com}$ ,  $R^2 = 0.67$ ) was then used as a

357 maximum benchmark and the thirteen remaining models also included in the validation

analysis were tested against the maximum benchmark using Fisher's z transformation (Rasch

et al., 1978). All of the models performed as well as the maximum benchmark model in the

validation analysis (P < 0.05;  $R^2 = 0.59$  to 0.66). This left fourteen models for consideration

361 as predictors of IMF, five of which used SCTS information and nine which used a

362 combination of SCTS information and reference information. Details of the final selected

363 prediction models developed from the entire data set are presented in Table 6. These included

364 Models B<sup>sp</sup>, F<sup>sp</sup>, H<sup>sp</sup>, J<sup>sp</sup> and L<sup>sp</sup> using SCTS information and models B<sup>com</sup>, F<sup>com</sup>, H<sup>com</sup>, J<sup>com</sup>,

365  $K^{com}$ ,  $L^{com}$ ,  $N^{com}$ ,  $O^{com}$  and  $P^{com}$  using a combination of information from both the reference

scans and SCTS.

373

#### 374 **4. Discussion**

- 375 It has been demonstrated in previous studies that information from single or multiple CT
- scans can provide moderately accurate predictions of IMF in different sheep breeds.
- Prediction accuracies range from  $R^2 = 0.33$  to 0.68. (Clelland et al., 2014; Karamichou,

Richardson, Nute, McLean, & Bishop, 2006; Lambe, McLean, et al., 2010; J. Macfarlane,
Lewis, Emmans, Young, & Simm, 2006) These studies have provided evidence of the
potential use of single-slice CT scanning as a predictor of IMF in different sheep breeds.
The results from this study provide evidence that further improvements in the prediction of
IMF are possible and the use of information from both spiral CT scans and a combination of
spiral CT scans and reference scans can adequately predict intramuscular fat content in the
loin of purebred Texel sheep.

385

386 Prediction models using CT parameters in the assessment of IMF content, achieved a maximum accuracy of  $AdjR^2 = 0.70$  and 0.71, using either spiral information only, or a 387 combination of spiral and reference scan information respectively. The results from this study 388 389 indicate that there are several potential prediction models that may be developed, using different combinations of CT parameters. There was a group of potential prediction models 390 with increasing degrees of complexity that had similar prediction accuracies for IMF, which 391 could be indicative of a possible 'ceiling' in the achievable prediction accuracies we may 392 expect using these types of CT parameters. Models that included increasing numbers of 393 independent variables appeared to be slightly less transferable when validated against the 394 independent time series data. Although not significant, the models including fewer 395 396 independent variables and more direct measures of soft tissue density (average and standard 397 deviation) were generally more robust during validation. This suggests that the complexity of the model may have an effect on the accuracy of prediction when applied to an independent 398 data set. 399

400

401 Given that there are few, if indeed any, *in vivo* predictors of MQ traits in meat producing 402 species, prediction accuracies may be acceptable with a suggested lower limit of  $R^2 = 0.30$ .

403 However in this study the use of CT parameters failed to adequately estimate shear force of the loin producing an upper limit of  $R^2 = 0.13$ . Similar studies carried out by Lambe et al. 404 (2008) and Karamichou et al. (2006) reported low phenotypic correlations between two 405 406 dimensional CT parameters and shear force (r = 0.15 - 0.22, r = 0.16 respectively). Although IMF is regarded as an important factor in the eating quality of meat when related to mouth 407 feel, tenderness, juiciness and species-specific flavor, the relationship between shear force 408 409 and IMF is less clear. Other factors such as cooking loss, ultimate pH, post-mortem glycolosis and conditioning (ageing) play an important role in the conversion of muscle to 410 411 meat and may have significant effects on shear force results. The CT parameters of the same muscle in vivo to that of a processed, aged and cooked piece of meat may be too far removed 412 for shear force parameter estimation or prediction to be possible. There is evidence of a linear 413 414 relationship between shear force values in cooked meat samples and solvent-extracted IMF 415 content in raw meat samples and it is generally accepted that this relationship exists (Hopkins, Hegarty, Walker, & Pethick, 2006; Pannier et al., 2014; Safari, Fogarty, Ferrier, 416 417 Hopkins, & Gilmour, 2001), although the size of the effect is often debated. Breeding programs in the UK for several species of livestock have resulted in substantial 418 419 genetic improvement in areas such as production efficiency. Genetic improvement in such traits are permanent and cumulative (Simm, 1998). CT predictions of carcass fat and muscle 420 421 weights and muscularity in both the gigot and loin have been used in pedigree UK sheep 422 breeding programmes over the last two decades (L. Bünger, J.M. Macfarlane, N. R. Lambe, J. Conington, K. A. McLean, K. Moore, 2011). Together with ultrasound measures of fat and 423 muscle depth in the loin region, CT measured carcass fat and muscle weights have 424 425 contributed much to the success of breeding for leaner carcasses (Moore, McLean, & Bunger, 2011). However, it remains that the drive for reduced carcass fatness and increased 426 427 muscularity in current breeding programmes is having an impact on IMF content and as a

result meat eating quality traits (Pannier et al., 2014). This study shows that there may be
several approaches using SCTS technology to predict IMF as a MQ trait and a proxy for meat
eating quality traits.

431

In conclusion, the prediction of mechanical shear force could not be achieved at an 432 acceptable level of accuracy employing information from SCTS information, or a 433 combination of reference scan image information and SCTS information. However, the 434 prediction of IMF in the loin employing information from SCTS with or without additional 435 436 information from reference scans was more promising. This study provides valuable evidence that the prediction of IMF and related meat eating quality traits for Texel lambs *in vivo* can be 437 achieved using spiral x-ray CT technology. However the increase in accuracy when 438 439 employing SCTS technology was not significant when compared to previous studies using single slice scanning procedures (P < 0.05; Clelland et al., 2014). This suggests that the use 440 of SCTS technology in the prediction of IMF does not adequately increase prediction 441 accuracies to justify additional image analysis involved in the processing of the resulting 442 data. Therefore the authors conclude that although the methods used in this study were 443 successful in the prediction of IMF, the increased image analysis and processing currently 444 required does not justify the increase in accuracy achieved when compared to current 445 446 reference scan procedures.
