ABSTRACT

This paper proposes an Adaptive Asynchronous Parallel (AAP) model for graph computations. As opposed to Bulk Synchronous Parallel (BSP) and Asynchronous Parallel (AP) models, AAP reduces both stragglers and stale computations by dynamically adjusting relative progress of workers. We show that BSP, AP and Stale Synchronous Parallel model (SSP) are special cases of AAP. Better yet, AAP optimizes parallel processing by adaptively switching among these models at different stages of a single execution. Moreover, employing the programming model of GRAPE, AAP aims to parallelize existing sequential algorithms based on fixpoint computation with partial and incremental evaluation. Under a monotone condition, AAP guarantees to converge at correct answers if the sequential algorithms are correct. Furthermore, we show that AAP can optimally simulate MapReduce, PRAM, BSP, AP and SSP. Using real-life and synthetic graphs, we experimentally verify that AAP outperforms BSP, AP and SSP for a variety of graph computations.

Figure 1: Runs under different parallel models

soon become stale due to more up-to-date messages. Stale computations are often redundant and increase unnecessary computation and communication costs. It is also observed that AP makes it hard to write, debug and analyze programs [50], and complicates the consistency analysis (see [54] for a survey).

A recent study shows that neither AP nor BSP consistently outperforms the other for different algorithms, input graphs and cluster scales [52]. For many graph algorithms, different stages in a single execution demand different models for optimal performance.

To rectify the problems, revisions of BSP and AP have been studied, notably Stale Synchronous Parallel (SSP) [30] and a hybrid model Hsync [52]. SSP relaxes BSP by allowing fastest workers to outpace the slowest ones by a fixed number c of steps (bounded staleness). It reduces stragglers, but incurs redundant stale computations. Hsync suggests to switch between AP and BSP, but it requires to predict switching points and incurs switching costs.

Is it possible to have a simple parallel model that inherits the benefits of BSP and AP, and reduces both stragglers and stale computations, without explicitly switching between the two? Better still, can the model retain BSP programming, ensure consistency, and guarantee correct convergence under a general condition?

AAP. To answer the questions, we propose Adaptive Asynchronous Parallel (AAP) model. Without global synchronization barriers, AAP is essentially asynchronous. As opposed to BSP and AP, each worker under AAP maintains parameters to measure (a) its progress relative to other workers, and (b) changes accumulated by messages (staleness). Each worker has immediate access to incoming messages, and decides whether to start the next round of computation based on its own parameters. In contrast to SSP, each worker dynamically adjusts its parameters based on its relative progress and message staleness, instead of using a fixed bound.

Example 1: Consider a computation task being conducted at three workers, where workers $P_1$ and $P_2$ take 3 time units to do one round of computation, $P_3$ takes 6 units, and it takes 1 unit to pass messages. This is carried out under different models as follows, as shown in Fig. 1(a) (it depicts runs for computing connected components shown in Fig. 1(b), to be elaborated in Example 4).

(1) BSP. As depicted in Fig. 1(a) (1), worker $P_3$ takes twice as long as $P_1$ and $P_2$, and it is a straggler. Due to its global synchronization, each superstep takes 6 time units, the speed of the slowest $P_3$. 
We present the programming model of AAP. Using real-life and synthetic graphs, we evaluate when to start the next round based on the progress of others. As (single-machine) graph algorithms with message declarations, and can be migrated to AAP when the sequential algorithms are correct. i.e., guarantees (a) convergence at correct answers, and (b) the Church-Rosser property. We also show that AAP+ is a simultaneous fixpoint computation and the Church-Rosser property. We also show that AAP+ can optimally simulate MapReduce, PRAM, BSP, AP and SSP. (4) AAP programming. We show that a variety of graph computations can be easily carried out by AAP (Section 5). These include shortest paths (SSSP), connected components (CC), collaborative filtering (CF) and PageRank (PageRank).

(3) SSP. Consider bounded staleness of 1, i.e., the fastest worker can outpace the slowest one by at most 1 round. As shown in Fig. 1(a)(3), P1 and P2 are not blocked by the straggler in the first 3 rounds. However, like AP, the second round of P3 is stale. Moreover, P1 and P2 cannot start their rounds 4 and 5 until P3 finishes its rounds 2 and 3, respectively, due to the bounded staleness condition. As a result, P1, P2 and P3 behave like in BSP model after clock time 14.

AAP reduces stragglers by not blocking fast workers. This is particularly helpful when the computation is CPU-intensive and skewed, when an evenly partitioned graph becomes skewed due to updates, or when we cannot afford evenly partitioning a large graph due to the partition cost. Moreover, AAP activates a worker only after it receives sufficient up-to-date messages and thus reduces redundant stale computations. This allows us to reallocate resources to useful computations via workload adjustments.

In addition, AAP differs from previous models in the following.

(1) Model switch. BSP, AP and SSP are special cases of AAP with fixed parameters. Hence AAP can naturally switch among these models at different stages of the same execution, without asking for explicit switching points or incurring the switching costs. As will be seen later, AAP is more flexible: some worker groups may follow BSP, while at the same time, the others run AP or SSP.

(2) Programming paradigm. AAP works with the programming model of GRAPE [24]. It allows users to extend existing sequential (single-machine) graph algorithms with message declarations, and parallelizes the algorithms across a cluster of machines. It employs aggregate functions to resolve conflicts raised by updates from different workers, without worrying about race conditions or requiring extra efforts to enforce consistency by using, e.g., locks [54].

(3) Convergence guarantees. AAP is modeled as a simultaneous fixpoint computation. Based on this we develop one of the first conditions under which AAP parallelization of sequential algorithms guarantees (a) convergence at correct answers, and (b) the Church-Rosser property, i.e., all asynchronous runs converge at the same result, as long as the sequential algorithms are correct.

(4) Expressive power. Despite its simplicity, AAP can optimally simulate MapReduce [20], PRAM (Parallel Random Access Machine) [49], BSP, AP and SSP. That is, algorithms developed for these models can be migrated to AAP without increasing the complexity.

(5) Performance. AAP outperforms BSP, AP and SSP for a variety of graph computations. As an example, for PageRank [15] and SSSP (single-source shortest path) on Friendster [1] with 192 workers, Table 1 shows the performance of (a) Giraph [2] (an open-source version of Pregel) and GraphLab [38] under BSP, (b) GraphLab and Maiter [57] under AP, (c) GiraphUC [28] under BAP, (d) PowerSwitch [52] under Hsys, and (e) GRAPE+, an extension of GRAPE by supporting AAP. GRAPE+ does better than these systems.

**Contributions and organization.** This paper introduces AAP, from foundations to implementation and empirical evaluation.

(1) Programming model. We present the programming model of GRAPE (Section 2). We show that it works well with AAP.

(2) AAP. We propose AAP (Section 3). We show that AAP subsumes BSP, AP and SSP as special cases, and reduces both stragglers and stale computations by adjusting relative progress of workers.

(3) Foundation. We model AAP as a simultaneous fixpoint computation with partial evaluation and incremental computation (Section 4). We provide a condition under which AAP guarantees termination and the Church-Rosser property. We also show that AAP can optimally simulate MapReduce, PRAM, BSP, AP and SSP.

(4) AAP programming. We show that a variety of graph computations can be easily carried out by AAP (Section 5). These include shortest paths (SSSP), connected components (CC), collaborative filtering (CF) and PageRank (PageRank).

(5) Implementation. As proof of concept, we develop GRAPE+ by extending GRAPE [23] from BSP to AAP (Section 6).

(6) Experiments. Using real-life and synthetic graphs, we evaluate the performance of GRAPE+ (Section 7), compared with the state-of-the-art graph systems listed in Table 1, and Petuum [53], a parameter server under SSP. Over real-life graphs and with 192 workers, (a) GRAPE+ is at least 2.6, 4.8, 3.2 and 7.9 times faster than these systems for SSSP, CC, PageRank and CF, respectively, up to 4127, 1635, 446 and 51 times. It incurs communications costs as small as 0.0001%, 0.027%, 0.13% and 57.7%, respectively. (b) On average AAP outperforms BSP, AP and SSP by 4.8, 1.7 and 1.8 times in response time, up to 27.4, 3.2 and 5.0 times, respectively. Over larger synthetic graphs with 10 billion edges, it is on average 4.3, 14.7 and 4.7 times faster, respectively. (c) GRAPE+ is on average 2.37, 2.68, 2.17 and 2.3 times faster for SSSP, CC, PageRank and CF, respectively, when the number of workers varies from 64 to 192.

**Related work.** Several parallel models have been studied for graphs. PRAM [49] supports parallel RAM access with shared memory, not for the shared-nothing architecture that is used nowadays.
MapReduce [20] is adopted by, e.g., GraphX [27]. However, it is not very efficient for iterative graph computations due to its blocking and I/O costs. BSP [48] with vertex-centric programming works better for graphs as shown by [39]. However, it suffers from straw- glers. As remarked earlier, AP reduces stragglers, but it comes with redundant state computation. It also bears with race conditions and their locking/unblocking costs, and complicates the convergence analysis (see Section 4.1) and programming [50].

Several graph systems under these models are in place, e.g., Pregel [39], GPS [44], Giraph++ [47], GRAPE [24] under BSP; GraphLab [26, 38], Maiter [57], GRACE [50] under (revised) AP; parameter servers under SSP [30, 37, 45, 51, 53]; GiraphUC [28] under BAP; and PowerSwitch under Hsync [52]. Blogel [55] works like AP within blocks, and in BSP across blocks. Most of these are vertex-centric. While Giraph++ and Blogel [47] process blocks [47], they inherit vertex-centric programming by treating blocks as vertices. GRAPE parallelizes sequential graph algorithms as a whole.

AAP differs from the prior models in the following.

(1) AAP reduces (a) stragglers of BSP via asynchronous message passing, and (b) redundant state computations of AP by imposing a bound (delay stretch), for workers to wait and accumulate updates. AAP is not vertex-centric. It is based on fixpoint computation, which simplifies the convergence and consistency analyses of AP.

(2) SSP mainly targets machine learning, with different correctness criteria. When accelerating graph computations is concerned, in contrast to SSP, (a) AAP reduces redundant state computations by enforcing a “lower bound” on accumulated messages, which also serves as an “upper bound” to support bounded staleness if needed. As will be seen in Section 3, performance can be improved when stragglers are forced to wait, rather than to catch up as suggested by SSP. (b) AAP dynamically adjusts the bound, instead of using a predefined constant. (c) Bounded staleness is not needed by SSP, CC, and PageRank as will be seen in Section 5.3.

(3) Similar to Maiter, AAP aggregates changes accumulated. As opposed to Maiter, it reduces redundant computations by (a) imposing a delay stretch on workers, to adjust their relative progress, (b) dynamically adjusting the bound to optimize performance, and (c) combining incremental evaluation with accumulative computation. AAP operates on graph fragments, while Maiter is vertex-centric.

(4) Both BAP and AAP reduce unnecessary messages. However, AAP achieves this by operating on fragments (blocks), and moreover, optimizes performance by adjusting relative progress of workers.

(5) Closer to AAP is Hsync, and PowerSwitch has the closest performance to GRAPE+. As opposed to Hsync, AAP does not demand complete switch from one mode to another. Instead, each worker may decide its own “mode” based on its relative progress. As will be seen in Section 3, fast workers may follow BSP within a group, while meanwhile, the other workers may adopt AP. Moreover, the parameters are adjusted dynamically, and hence AAP does not have to predict switching points and pay the price of switching cost.

Close to this work is GRAPE [24]. AAP adopts the programming model of GRAPE, and GRAPE+ extends GRAPE. However, (1) the objective of this work is to introduce AAP and to explore appropriate models for graph computation. In contrast, GRAPE adopts BSP. (2) We show that as an asynchronous model, AAP retains the programming paradigm and ease of consistency control of GRAPE. (3) We identify a condition for AAP to converge at correct results and have the Church-Rosser property, which is not an issue for GRAPE. (4) We prove stronger simulation results (see Section 4.2). Moreover, AAP can optimally simulate BSP, AP, SSP and GRAPE (Section 4.2). (5) We evaluate GRAPE+ and GRAPE by comparing with graph systems of different models, while the experimental study of [24] focused on synchronous systems only.

There has also been work on mitigating the straggler problem, e.g., dynamic repartitioning [13, 33, 40], work stealing [10, 14], shedding [21], LATE [56], and fine-grained partition [17]. AAP is complementary to these methods, to reduce stragglers and state computation by adjusting relative progress of workers.

2 THE PROGRAMMING MODEL

AAP adopts the programming model of [24], which we review next. As will be seen in Section 3, AAP is able to parallelize sequential graph algorithms just like GRAPE. That is, the asynchronous model does not make programming harder than GRAPE.

Graph partition. AAP supports data-partitioned parallelism. It is to work on graphs partitioned into smaller fragments.

Consider graphs $G = (V, E, L)$, directed or undirected, where (1) $V$ is a finite set of nodes; (2) $E \subseteq V \times V$ is a set of edges; and (3) each node $v \in V$ (resp. edge $e \in E$) is labeled with $L(v)$ (resp. $L(e)$) indicating its content, as found in property graphs.

Given a natural number $m$, a strategy $P$ partitions $G$ into fragments $F = (F_1, \ldots, F_m)$ such that each $F_i = (V_i, E_i, L_i)$ is a subgraph of $G$, $V = \bigcup_{i \in [1,m]} V_i$, and $E = \bigcup_{i \in [1,m]} E_i$. Here $F_i$ is called a subgraph of $G$ if $V_i \subseteq V$, $E_i \subseteq E$, and for each node $v \in V_i$ (resp. edge $e \in E_i$), $L_i(v) = L(v)$ (resp. $L_i(e) = L(e)$). Note that $F_i$ is a graph itself, but is not necessarily an induced subgraph of $G$.

AAP allows users to pick a edge-cut [11] or vertex-cut [34] strategy $P$ to partition a graph $G$. When $P$ is edge-cut, a cut edge from $F_i$ to $F_j$ has a copy in both $F_i$ and $F_j$. Denote by

(a) $F_i.I$ (resp. $F_i.O$) the set of nodes $v \in V_i$ such that there exists an edge $(v', v)$ (resp. $(v, v')$) with a node $v'$ in $F_j$ $(i \neq j)$; and

(b) $F_i.O$ (resp. $F_i.I$) the set of nodes $v'$ in some $F_j$ $(i \neq j)$ such that there exists an edge $(v, v')$ (resp. $(v', v)$) with $v \in V_i$.

We refer to the nodes in $F_i.I \cup F_i.O$ as the border nodes of $F_i$ w.r.t. $P$. For vertex-cut, border nodes are those that have copies in different fragments. In general, a node $v$ is a border node if $v$ has an adjacent edge across two fragments, or a copy in another fragment.

Programming. Using our familiar terms, we refer to a graph computation problem as a class $Q$ of graph queries, and instances of the problem as queries of $Q$. Following [24], to answer queries $Q \in Q$ under AAP, one only needs to specify three functions.

(1) PEval: a sequential algorithm for $Q$ that given a query $Q \in Q$ and a graph $G$, computes the answer $Q(G)$.
Consider Example 2:

For each $v \in V_I$:
1. $C := \text{DFS}(F_I)$; /* find local connective components by DFS */
2. for each $C \subseteq C$ do
3. create a new "root" node $v_C$;
4. $v_c, \text{cid} := \min \{v, \text{id} \mid v \in C\}$;
5. for each $v \in C$ do
6. link $v$ to $v_C$; $v._\text{root} := v_C$; $v.\text{cid} := v_c, \text{cid}$;
7. $Q(F_I) := \{v.\text{cid} \mid v \in V_I\}$;

Message segment: $M_{i,j} := \{v.\text{cid} \mid v \in F_I \cap F_J; i, j \neq i\}$

$f_{\text{agg}}(v) := \min(v.\text{cid})$

Figure 2: PEval for CC under AAP

(2) IncEval: a sequential incremental algorithm for $Q$ that given $Q, G, Q(G)$ and updates $\Delta G$ to $G$, computes updates $\Delta O$ to the old output $Q(G)$ such that $Q(G \oplus \Delta G) = Q(G) \oplus \Delta O$, where $G \oplus \Delta G$ denotes $G$ updated by $\Delta G$ [43].

Here IncEval only needs to deal with changes $\Delta G$ to update parameters (status variables) to be defined shortly.

(3) Assemble: a function that collects partial answers computed locally at each worker by PEval and IncEval, and assembles the partial results into complete answer $Q(G)$.

Taken together, the three functions are referred to as a PIE program for $Q$, PEval, IncEval and Assemble. PEval and IncEval can be existing sequential (incremental) algorithms for $Q$, which are to operate on a fragment $F_I$ of $G$ partitioned via a strategy $P$.

The only additions are the following declarations in PEval.

(a) Update parameters. PEval declares status variables $x$ for a set $C_i$ in a fragment $F_I$, to store contents of $F_I$ or partial results of a computation. Here $C_i$ is a set of nodes and edges within $d$-hops of the nodes in $F_I$, $I \cup F_I, O'$ for an integer $d$. When $d = 0$, $C_i$ is $F_I, I \cup F_I, O'$.

We denote by $C_i, x$ the set of update parameters of $F_I$, which consists of status variables associated with the nodes and edges in $C_i$. As will be seen in Section 3, the variables in $C_i, x$ are the candidates to be updated by incremental steps IncEval.

(b) Aggregate functions. PEval also specifies an aggregate function $f_{\text{agg}}$, e.g., $\min$ and $\max$, to resolve conflicts when multiple workers attempt to assign different values to the same update parameter. These are specified in PEval and are shared by IncEval.

Example 2: Consider graph connectivity (CC). Given an undirected graph $G = (V, E, L)$, a subgraph $G_s$ of $G$ is a connected component of $G$ if (a) it is connected, i.e., for any two nodes $v$ and $v'$ in $G_s$, there exists a path between $v$ and $v'$, and (b) it is maximum, i.e., adding any node of $G$ to $G_s$ makes the induced subgraph disconnected.

For each $G, CC$ has a single query $Q$, to compute all connected components of $G$, denoted by $Q(G)$. CC is in $O(|G|)$ time [12].

AAP parallelsizes CC with the same PEval and IncEval of GRAPE [24]. More specifically, a PIE program $P$ is given as follows.

(1) As shown in Fig. 2, at each fragment $F_I$, PEval uses a sequential CC algorithm (Depth-First Search, DFS) to compute the local connected components and create their ids, except that it declares the following (underlined): (a) for each node $v \in V_I$, an integer variable $v.\text{cid}$, initially $v.\text{id}$; (b) $F_I, O$ as the candidate set $C_i$, and $C_i, x = \{v.\text{cid} \mid v \in F_I, O\}$ as the update parameters; and (c) $\min$ as an aggregate function $f_{\text{agg}}$; if there are multiple values for the same $v.\text{cid}$, the smallest value is taken by the linear order on integers.

For each local connected component $C$, a PEval creates a "root" node $v_C$ carrying the minimum node id in $C$ as $v_c.\text{cid}$, and (b) links all the nodes in $C$ to $v_C$ and sets their cid as $v_c.\text{cid}$. These can be done in one pass of the edges in fragment $F_I$ via DFS.

(2) Given a set $M_i$ of changed ids of border nodes, IncEval incrementally updates local components in $F_I$ by "merging" components when possible. As shown in Fig. 3, by using $\min$ as $f_{\text{agg}}$, it (a) updates the cid of each border node to the minimum one; and (b) propagates the change to its root $v_c$ and all border nodes linked to $v_c$.

(3) Assemble first updates the cid of each node to the cid of its linked root. It then merges all the nodes having the same cids in a single bucket, and returns all buckets as connected components.

We remark the following about the programming paradigm.

(1) There have been methods for incrementalizing graph algorithms, to get incremental algorithms from their batch counterparts [9]. Moreover, it is not hard to develop IncEval by revising a batch algorithm in response to changes to update parameters, as shown by the cases of CC (Example 4) and PageRank (Section 5.3).

(2) We adopt edge-cut in the sequel unless stated otherwise; but AAP works with other partition strategies. Indeed, as will be seen in Section 4, the correctness of asynchronous runs under AAP remains intact under the conditions given there, regardless of partitioning strategy used. Nonetheless, different strategies may yield partitions with various degrees of skewness and stragglers, which have an impact on the performance of AAP, as will be seen in Section 7.

(3) The programming model aims to facilitate users to develop parallel programs, especially for those who are more familiar with conventional sequential programming. This said, programming with GRAPE still requires domain knowledge of algorithm design, to declare update parameters and design an aggregate function.

3 THE AAP MODEL

We next present the adaptive asynchronous parallel model (AAP).

Setting. Adopting the programming model of GRAPE (Section 2), to answer a class $Q$ of queries on a graph $G$, AAP takes as input a PIE program $P$ (i.e., PEval, IncEval, Assemble) for $Q$, and a partition strategy $P$. It partitions $G$ into fragments $(F_1, \ldots, F_m)$ using $P$, such that each fragment $F_i$ resides at a virtual worker $P_i$ for $i \in \{1, \ldots, m\}$.
Upon receiving \( Q(F) \), each worker \( P_i \) in parallel. After this, \( P_{\text{Eval}} \) generates a message \( M_{(i,j)} \) and sends it to worker \( P_j \) for \( j \in [1, m], j \neq i \).

**Message passing.** After each round of computation at worker \( P_i \), \( P_i \) collects update parameters of \( C_i, \bar{x} \) with changed values in a set \( \Delta C_i, \bar{x} \). It groups \( \Delta C_i, \bar{x} \) into \( M_{(i,j)} \) for \( j \in [1, m] \) and \( j \neq i \), where \( M_{(i,j)} \) includes \( v, x \in \Delta C_i, \bar{x} \) for \( v \in C_j \), i.e., \( x \) also resides in fragment \( F_j \). That is, \( M_{(i,j)} \) includes changes of \( C_i, \bar{x} \to \) the update parameters \( C_j, \bar{x} \) or \( F_j \). It sends \( M_{(i,j)} \) as a message to worker \( P_j \).

Messages \( M_{(i,j)} \) are referred to as designated messages in [24]. More specifically, each worker \( P_i \) maintains the following:

1. An index \( I_l \) that given a border node \( v \), retrieves the set of \( j \in [1, m] \) such that \( v \in F_j, \bar{F}_j \cup F_j, O \) and \( i \neq j \), i.e., where \( v \) resides; it is deduced from the strategy \( P \); and
2. A buffer \( B_{x_i} \), to keep track of messages from other workers.

As opposed to GRAPE, AAP is asynchronous in nature. (1) AAP adopts (a) point-to-point communication: a worker \( P_i \) can send a message \( M_{(i,j)} \) directly to worker \( P_j \), and (b) push-based message passing: \( P_i \) sends \( M_{(i,j)} \) to worker \( P_j \) as soon as \( M_{(i,j)} \) is available, regardless of the progress at other workers. A worker \( P_i \) can receive messages \( M_{(i,j)} \) at any time, and saves it in its buffer \( B_{x_j} \), without being blocked by supersteps. (2) Under AAP, master \( P_0 \) is only responsible for making decision for termination and assembling partial answers by Assemble (see details below). (3) Workers exchange their status to adjust relative progress (see below).

**Parameters.** To reduce stragglers and redundant stale computations, each (virtual) worker \( P_i \) maintains a delay stretch \( D_{Si} \) such that \( P_i \) is put on hold for \( D_{Si} \) time to accumulate updates. Stretch \( D_{Si} \) is dynamically adjusted by a function \( \delta \) based on the following.

1. Staleness \( \eta_i \), measured by the number of messages in buffer \( B_{x_i} \) received by \( P_i \) from distinct workers. Intuitively, the larger \( \eta_i \) is, the more messages are accumulated in \( B_{x_i} \) and hence, the earlier \( P_i \) should start the next round of computation. (2) Bounds \( r_{\text{min}} \) and \( r_{\text{max}} \), the smallest and largest rounds being executed at all workers, respectively. Each \( P_i \) keeps track of its current round \( r_i \). These are to control the relative speed of workers.

For example, to simulate SSP [30], when \( r_i \leq r_{\text{max}} \) and \( r_i - r_{\text{min}} > e \), we can set \( D_{Si} = +\infty \), to prevent \( P_i \) from moving too far ahead.

We will present adjustment function \( \delta \) for \( D_{Si} \) shortly.

**Parallel model.** Given a query \( Q \in Q \) and a partitioned graph \( G \), AAP posts the same query \( Q \) to all the workers. It computes \( Q(G) \) in three phases as shown in Fig. 4, described as follows.

1. **Partial evaluation.** Upon receiving \( Q, P_{\text{Eval}} \) computes partial results \( Q(F) \) at each worker \( P_i \) in parallel. After this, \( P_{\text{Eval}} \) generates a message \( M_{(i,j)} \) and sends it to worker \( P_j \) for \( j \in [1, m], j \neq i \).

More specifically, \( M_{(i,j)} \) consists of triples \( (x, \text{val}, r) \), where \( x \in C_i, \bar{x} \) is associated with a node \( v \) that is in \( C_j \cup C_j \), and \( C_j \) is deduced from the index \( I_l; \) \( \text{val} \) is the value of \( x \), and \( r \) indicates the round when \( x \) is computed.

Worker \( P_i \) receives messages from other workers at any time and stores the messages in its buffer \( B_{x_i} \). (2) **Incremental evaluation.** In this phase, \( P_{\text{Eval}} \) iterates until the termination condition is satisfied (see below). To reduce redundant computation, \( P_{\text{Eval}} \) adjusts (a) relative progress of workers and (b) work assignments. More specifically, \( P_{\text{Eval}} \) works as follows.

1. **IncEval** is triggered at worker \( P_i \) to start the next round if (a) \( B_{x_i} \) is nonempty, and (b) \( P_i \) has been suspended for \( D_{Si} \) time. Intuitively, \( P_{\text{Eval}} \) is invoked only if changes are inflicted to \( C_i, \bar{x} \), i.e., \( B_{x_i} \neq \emptyset \), and only if \( P_i \) has accumulated enough messages.

2. **When \( P_{\text{Eval}} \) is triggered at \( P_i \), it does the following:**
   - compute \( M_i = f_{\text{agg}}(B_{x_i} \cup C_i, \bar{x}), i.e., P_{\text{Eval}} \) applies the aggregate function to \( B_{x_i} \cup C_i, \bar{x} \), to deduce changes to its local update parameters; and it clears buffer \( B_{x_i} \);
   - incrementally compute \( Q(F_j \cup M_i) \) with \( P_{\text{Eval}} \), by treating \( M_i \) as updates to its local fragment \( F_j \); and
   - derive messages \( M_{(i,j)} \) that consists of updated values of \( C_i, \bar{x} \) for border nodes that are in both \( C_i \) and \( C_j \), for all \( j \in [1, m], j \neq i \); it sends \( M_{(i,j)} \) to worker \( P_j \).

In the entire process, \( P_i \) keeps receiving messages from other workers and saves them in its buffer \( B_{x_i} \). No synchronization is imposed.

When \( P_{\text{Eval}} \) completes its current round at \( P_i \) or when \( P_i \) receives a new message, \( D_{Si} \) is adjusted. The next round of \( P_{\text{Eval}} \) is triggered if the conditions (a) and (b) in (1) above are satisfied; otherwise \( P_i \) is suspended for \( D_{Si} \) time, and its resources are allocated to other (virtual) workers \( P_j \) to do useful computation, preferably to \( P_j \) that is assigned to the same physical worker as \( P_i \) to minimize the overhead for data transfer. When the suspension of \( P_j \) exceeds \( D_{Si} \), \( P_i \) is activated again to start the next round of \( P_{\text{Eval}} \).

3. **Termination.** When \( P_{\text{Eval}} \) is done with its current round of computation, if \( B_{x_i} = \emptyset \), \( P_i \) sends a flag inactive to master \( P_0 \) and becomes inactive. Upon receiving inactive from all workers, \( P_0 \) broadcasts a message terminate to all workers. Each \( P_i \) may respond with either ack if it is inactive, or wait if it is active or is in the queue for execution. If one of the workers replies wait, the iterative incremental step proceeds (phase (2) above).

Upon receiving ack from all workers, \( P_0 \) pulls partial results from all workers, and applies Assemble to the partial results. The outcome is referred to as the result of the parallelization of \( \rho \) under \( P \), denoted by \( \rho(Q, G) \). AAP returns \( \rho(Q, G) \) and terminates.

**Example 3:** Recall the PIE program \( \rho \) for CC from Example 2.

![Figure 4: Workflow of AAP](image-url)
Under AAP, it works in three phases as follows.

1. **PEval** computes connected components and their cids at each fragment $F_i$ by using DFS. At the end of the process, the cids of border nodes are grouped as messages and sent to neighboring workers. More specifically, for $j \in [1, m]$, $\{v, cid \mid v \in F_i \cap F_j\}$ is sent to worker $P_j$ as message $M_{(i,j)}$ and is stored in buffer $B_{S_j}$.

2. **IncEval** first computes updates $M_i$ by applying min to changed cids in $B_{S_i} \cup C_i$, $\bar{x}$, when it is triggered at worker $P_i$ as described above. It then incrementally updates local components in $F_i$ starting from $M_i$. At the end of the process, the changed cids are sent to neighboring workers as messages, just like PEval does.

The process iterates until no more changes can be made.

3. **Assemble** is invoked at master at this point. It computes and returns connected components as described in Example 2.

The example shows that AAP works well with the programming model of GRAPE, i.e., AAP does not make programming harder.

**Special cases.** BSP, AP and SSP are special cases of AAP. Indeed, these can be carried out by AAP by specifying function $\delta$ as follows.

- **BSP:** function $\delta$ sets $DS_i = +\infty$ if $r_j > r_{\min}$, i.e., $P_i$ is suspended; otherwise $DS_i = 0$, i.e., $P_i$ proceeds at once; thus all workers are synchronized as no one can outpace the others.

- **AP:** function $\delta$ always sets $DS_i = 0$, i.e., worker $P_i$ triggers the next round of computation as soon as its buffer is nonempty.

- **SSP:** function $\delta$ sets $DS_i = +\infty$ if $r_j > r_{\min} + c$ for a fixed bound $c$ like in SSP, and sets $DS_i = 0$ otherwise. That is, the fastest worker may move at most $c$ rounds ahead.

Moreover, AAP can simulate Hsync [52] by using function $\delta$ to implement the same switching rules of Hsync.

**Dynamic adjustment.** AAP is able to dynamically adjust delay sketch $DS_i$ at each worker $P_i$; for example, function $\delta$ may define

$$DS_i = \begin{cases} +\infty & \text{if } r_j > r_{\min} \text{ or } r_{\max} \\ -S(r_j, r_{\min}, r_{\max}) \lor (\eta_i = 0) & \text{if } S(r_j, r_{\min}, r_{\max}) \land (1 \leq \eta_i < L_i) \\ 0 & \text{if } S(r_j, r_{\min}, r_{\max}) \land (\eta_i \geq L_i) \end{cases}$$

where the parameters of function $\delta$ are described as follows.

1. **Predicate $S(r_j, r_{\min}, r_{\max})$** is to decide whether $P_i$ should be suspended immediately. For example, under SSP, it is defined as false if $r_j = r_{\max}$ and $r_{\max} - r_{\min} > c$. When bounded staleness is not needed (see Section 5.3), $S(r_j, r_{\min}, r_{\max})$ is constantly true.

2. **Variable $L_i$** "predicts" how many messages should be accumulated, to strike a balance between stale-computation reduction and useful outcome expected from the next round of IncEval at $P_i$. AAP adjusts $L_i$ as follows. Users may opt to initialize $L_i$ with a uniform bound $L_+$, to start stale-computation reduction early (see Appendix B for an example). AAP adjusts $L_i$ at each round at $P_i$, based on (a) predicted running time $t_i$ of the next round, and (b) the predicted arrival rate $s_j$ of messages. When $s_j$ is above the average rate, $L_i$ is changed to $\max(\eta_i, L_+) + \Delta t_j + s_j$, where $\Delta t_j$ is a fraction of $L_j$, and $L_j$ is adjusted with the number of "fast" workers. We approximate $t_i$ and $s_j$ by aggregating statistics of consecutive rounds of IncEval. One can get more precise estimate by using a random forest model [31], with query logs as training samples.

3. **Variable $T^i_{lid}$** estimates how longer $P_i$ should wait to accumulate $L_i$ many messages. We approximate it as $\frac{L_i - \eta_i}{\bar{\mu}}$, using the number of messages that remain to be received, and message arrival rate $\bar{\mu}$. Finally, $T^i_{lid}$ is the idle time of worker $P_i$ after the last round of IncEval. We use $T^i_{lid}$ to prevent $P_i$ from indefinite waiting.

**Example 4:** As an instantiation of Example 1, recall the PTE program $\rho$ for CC from Example 2 and illustrated in Example 3. Consider a graph $G$ that is partitioned into fragments $F_1, F_2$ and $F_3$ and distributed across workers $P_1, P_2$ and $P_3$, respectively. As depicted in Fig. 1(b), (a) each circle represents a connected component, annotated with its cid, and (b) a dotted line indicates a cut edge between fragments. One can see that graph $G$ has a single connected component with the minimal vertex id 0. Suppose that workers $P_1, P_2$ and $P_3$ take 3, 3 and 6 time units, respectively.

One can verify the following by referencing Figure 1(a).

(a) Under BSP, Figure 1(a) (1) depicts part of a run of $P$, which takes 5 rounds for the minimal cid 0 to reach component 7.

(b) Under AP, a run is shown in Fig. 1(a) (2). Note that before getting cid 0, workers $P_1$ and $P_2$ invoke 3 rounds of IncEval and exchange cid 1 among components 1-4, while under BSP, one round of IncEval suffices to pass cid 0 from $P_3$ to these components. Hence a large part of the computations of faster $P_1$ and $P_2$ is stale and redundant.

(c) Under SSP with bounded staleness 1, a run is given in Fig. 1(a) (3). It is almost the same as Fig. 1(a) (2), except that $P_1$ and $P_2$ cannot start round 4 before $P_3$ finishes round 2. More specifically, when minimal cids in components 5 and 6 are set to 0 and 4, respectively, $P_1$ and $P_2$ have to wait for $P_3$ to set the cid of component 7 to 5. These again lead to unnecessary stale computations.

(d) Under AAP, $P_3$ can suspend IncEval until it receives enough changes as shown in Fig. 1(a) (4). For instance, function $\delta$ starts with $L_\perp = 0$. It sets $DS_i = 0$ if $|\eta_i| \geq 1$ for $i \in [1, 2]$ since no messages are predicted to arrive within the next time unit. In contrast, it sets $DS_i = 1$ if $|\eta_i| \leq 4$ since in addition to the 2 messages accumulated, 2 more messages are expected to arrive in 1 time unit; hence $\delta$ decides to increase $DS_i$. These delay stretches are estimated based on the running time (3, 3 and 6 for $P_1$, $P_2$ and $P_3$, respectively) and message arrival rates. With these delay stretches, $P_1$ and $P_2$ may proceed as soon as they receive new messages, but $P_3$ starts a new round only after accumulating 4 messages. Now $P_3$ only takes 2 rounds of IncEval to update all the cids in $F_3$ to 0. Compared with Figures 1(a) (1)–(3), the straggler reaches fixpoint in less rounds.

From our experimental study, we find that AAP reduces the costs of iterative graph computations mainly from three directions.

1. ** AAP reduces redundant stale computations and stragglers by adjusting relative progress of workers. In particular, (a) some computations are substantially improved when stragglers are forced to accumulate messages; this actually enables the stragglers to converge in less rounds, as shown by Example 4 for CC. (b) When the time taken by different rounds at a worker does not vary much (e.g., PageRank in Appendix B), fast workers are “automatically” grouped together after a few rounds and run essentially BSP within the group, while the group and slow workers run under AP. This shows that AAP is more flexible than Hsync [52].
(2) Like GRAPE, AAP employs incremental IncEval to minimize unnecessary recomputations. The speedup is particularly evident when IncEval is bounded [43], localizable or relatively bounded [22]. For instance, IncEval is bounded [42] if given $F_i, Q, Q(F_i)$ and $M_i$, it computes $\Delta O_i$ such that $Q(F_i @ M_i) < Q(F_i @ \Delta O_i)$, in cost that can be expressed as a function in $|M_i| + |\Delta O_i|$, the size of changes in the input and output; intuitively, it reduces the cost of computation on (possibly big) $F_i$ to a function of small $|M_i| + |\Delta O_i|$. As an example, IncEval for CC (Fig. 3) is a bounded incremental algorithm.

(3) Observe that algorithms PEval and IncEval are executed on fragments, which are graphs themselves. Hence AAP inherits all optimization strategies developed for the sequential algorithms.

4 Convergence and Expressive Power
As observed by [54], asynchronous executions complicate the convergence analysis. Nonetheless, we develop a condition under which AAP guarantees to converge at correct answers. In addition, AAP is generic. We show that parallel models MapReduce, PRAM, BSP, AP and SSP can be optimally simulated by AAP. Proofs of the results in this section can be found in Appendix.

4.1 Convergence and Correctness
Given a PIE program $p$ (i.e., PEval, IncEval, Assemble) for a class $Q$ of graph queries and a partition strategy $P$, we want to know whether the AAP parallelization of $p$ converges at correct results. That is, whether for all queries $Q \in Q$ and all graphs $G$, $p$ terminates under AAP over $G$ partitioned via $P$, and its result $\rho(Q, G) = Q(G)$.

We formalize termination and correctness as follows.

**Fixpoint.** Similar to GRAPE [24], AAP parallelizes a PIE program $p$ based on a simultaneous fixpoint operator $\phi(R_1, \ldots, R_m)$ that starts with partial evaluation of PEval and employs incremental function IncEval as the intermediate consequence operator:

$$R^0_i = \text{PEval}(Q, F_1^0[x_i]),$$

$$R^{i+1}_i = \text{IncEval}(Q, R^i_1, \ldots, R^i_m, M_i),$$

where $i \in [1, m]$. $R^i_i$ denotes partial results in round $r$ at worker $P_i$, fragment $F^i_i = F_i[x_i]$ is fragment $F_i$ at the end of round $r$ carrying update parameters $C_i, x_i$, and $M_i$ denotes changes to $C_i, x_i$ computed by $f_{agg}(\exists x_i \cup C_i, x_i)$ as we have seen in Section 3.

The computation reaches a fixpoint if for all $i \in [1, m]$, $R^{i+1}_i = R^i_i$, i.e., no more changes to partial results $R^i_i$ at any worker. At this point, Assemble is applied to $R^i_i$ for $i \in [1, m]$, and computes $\rho(Q, G)$. If so, we say that $p$ converges at $\rho(Q, G)$.

In contrast to synchronous execution, a PIE program $p$ may have different asynchronous runs. If IncEval is triggered in different orders at multiple workers depending on, e.g., partition of $G$, clusters and network latency. These runs may end up with different results [58]. A run of $p$ can be represented as traces of PEval and IncEval at all workers (see, e.g., Fig. 1(a)).

We say that $p$ terminates under AAP with $P$ if for all queries $Q \in Q$ and graphs $G$, all runs of $p$ converge at a fixpoint. We say that $p$ has the Church-Rosser property under AAP if all its asynchronous runs converge at the same result. We say that AAP correctly parallelizes $p$ if $p$ has the Church-Rosser property, i.e., it always converges at the same $\rho(Q, G)$, and $\rho(Q, G) = Q(G)$.

**Termination and correctness.** We now identify a monotone condition under which a PIE program is guaranteed to converge at correct answers under AAP. We start with some notation.

(1) We assume a partial order $\leq$ on partial results $R^i_1$. This contrasts with GRAPE [24], which defines partial order only on update parameters. The partial order $\leq$ is needed to analyze the Church-Rosser property of asynchronous runs under AAP. To simplify the discussion, assume that $R^i_1$ carries its update parameters $C_i, x_i$.

We define the following properties of IncEval.

- IncEval is contracting if for all queries $Q \in Q$ and fragmented graphs $G$ via $P$, $R^i_{1+1} \leq R^i_1$ for all $i \in [1, m]$ in the same run.
- IncEval is monotonic if for all queries $Q \in Q$ and graphs $G$, for all $i \in [1, m]$, if $R^i_1 \leq R^i_2$ then $R^i_{1+1} \leq R^i_{2+1}$, where $R^i_1$ and $R^i_2$ denote partial results in (possibly different) runs.

For instance, consider the PIE program $p$ for CC (Example 2). The order $\leq$ is defined on sets of connected components (CCs) in each fragment, such that $S_1 \leq S_2$ if for each CC $C_2$ in $S_2$, there exists a CC $C_1$ in $S_1$ with $C_2 \subseteq C_1$ and $cid_1 \leq cid_2$, where $cid_1$ is the id of $C_1$ for $i \in [1, 2]$. Then one can verify that the IncEval of $p$ is both contracting and monotonic, since $f_{agg}$ is defined as min.

(2) We want to identify a condition under which AAP correctly parallelizes a PIE program $p$ as long as its sequential algorithms PEval, IncEval and Assemble are correct, regardless of the order in which PEval and IncEval are triggered. We use the following.

We say that (a) PEval is correct if for all queries $Q \in Q$ and graphs $G$, PEval$(Q, G)$ returns $Q(G)$; (b) IncEval is correct if IncEval$(Q, Q(G), G, M)$ returns $Q(G @ M)$, where $M$ denotes messages (updates); and (c) Assemble is correct if when $p$ converges at round $r_0$ under SSP, Assemble$(R^0_1, \ldots, R^0_m) = Q(G)$. We say that $p$ is correct for $Q$ if PEval, IncEval and Assemble are correct for $Q$.

**A monotone condition.** We identify three conditions for $\rho$.

(T1) The values of updated parameters are from a finite domain.

(T2) IncEval is contracting.

(T3) IncEval is monotonic.

While conditions T1 and T2 are essentially the same as the ones for GRAPE [24], condition T3 does not find a counterpart in [24].

The termination condition of GRAPE remains intact under AAP.

**Theorem 1:** Under AAP, a PIE program $p$ guarantees to terminate with any partition strategy $P$ if it satisfies conditions T1 and T2.

These conditions are general. Indeed, given a graph $G$, the values of update parameters are often computed from the active domain of $G$ and are finite. By the use of aggregate function $f_{agg}$, IncEval is often contracting, as illustrated by the PIE program for CC above.

**Proof:** By T1 and T2, each update parameter can be changed finitely many times. This warrants the termination of $p$ since $p$ terminates when no more changes can be incurred to its update parameters.

However, the condition of GRAPE does not suffice to ensure the Church-Rosser property of asynchronous runs. For the correctness of a PIE program under AAP, we need condition T3 additionally.

**Theorem 2:** Under conditions T1, T2 and T3, AAP correctly parallelizes a PIE program $p$ for a query class $Q$ if $p$ is correct for $Q$, with any partition strategy $P$. 

\[\square\]
Proof: We show the following under the conditions. (1) Both the synchronous run of \(\rho\) under BSP and asynchronous runs of \(\rho\) under AAP reach a fixpoint. (2) No partial results of \(\rho\) under BSP are “larger” than any fixpoint of asynchronous runs. (3) No partial results of asynchronous runs are “larger” than the fixpoint under BSP. From (2) and (3) it follows that \(\rho\) has the Church-Rosser property. Hence AAP correctly parallelizes \(\rho\) as long as \(\rho\) is correct for Q. \(\Box\)

Recall that AP, BSP and SSP are special cases of AAP. From the proof of Theorem 2 we can conclude that as long as a PIE program \(\rho\) is correct for Q, \(\rho\) can be correctly parallelized

- under conditions T1 and T2 by BSP;
- under conditions T1, T2 and T3 by AP; and
- under conditions T1, T2 and T3 by SSP.

Novelty. As far as we are aware of, T1, T2 and T3 provide the first condition for asynchronous runs to converge and ensure the Church-Rosser property. To see this, we examine convergence conditions for GRAPE [24], Maiter [57], BAP [28] and SSP [19, 30]. (1) As remarked earlier, the condition of GRAPE does not ensure the Church-Rosser property, which is not an issue for BSP.

(2) Maiter [57] focuses on vertex-centric programming and identifies four conditions for convergence, on an update function \(f\) that changes the state of a vertex based on its neighbors. The conditions require that \(f\) is distributive, associative, commutative and moreover, satisfies an equation on initial values.

As opposed to [57], we deal with block-centric programming of which the vertex-centric model is a special case, when a fragment is limited to a single node. Moreover, the last condition of [57] is quite restrictive. Further, the proof of [57] does not suffice for the Church-Rosser property. A counterexample could be conditional convergent series, for which asynchronous runs may diverge [18, 35].

(3) It is shown that BAP can simulate BSP under certain conditions on message buffers [28]. It does not consider the Church-Rosser property, and we make no assumption about message buffers.

(4) Conditions have been studied to assure the convergence of stochastic gradient descent (SGD) with high probability [19, 30]. In contrast, our conditions are deterministic: under T1, T2 and T3, all AAP runs guarantee to converge at correct answers. Moreover, we consider AAP computations not limited to machine learning.

4.2 Simulation of Other Parallel Models

We next show that algorithms developed for MapReduce, PRAM, BSP, AP and SSP can be migrated to AAP without extra complexity. That is, AAP is as expressive as the other parallel models.

Note that while this paper focuses on graph computations, AAP is not limited to graphs as a parallel computation model. It is as generic as BSP and AP, and does not have to take graphs as input.

Following [49], we say that a parallel model \(M_1\) optimally simulates model \(M_2\) if there exists a compilation algorithm that transforms any program with cost \(C\) on \(M_2\) to a program with cost \(O(C)\) on \(M_1\). The cost includes computational and communication cost. That is, the complexity bound remains the same.

As remarked in Section 3, BSP, AP and SSP are special cases of AAP. From this one can easily verify the following.

Proposition 3: AAP can optimally simulate BSP, AP and SSP. \(\Box\)

By Proposition 3, algorithms developed for, e.g., Pregel [39], GraphLab [26, 38] and GRAPE [24] can be migrated to AAP. As an example, a Pregel algorithm \(\mathcal{A}\) (with a function \(compute()\) for vertices) can be simulated by a PIE algorithm \(\rho\) as follows. (a) PEval runs \(compute()\) over vertices with a loop, and uses status variable to exchange local messages instead of \(SendMessageTo()\) of Pregel. (b) The update parameters are status variables of border nodes, and function \(f_{agg}\) groups messages just like Pregel, following BSP. (c) IncEval also runs \(compute()\) over vertices in a fragment, except that it starts from active vertices (border nodes with changed values).

We next show that AAP can optimally simulate MapReduce and PRAM. It was shown in [24] that GRAPE can optimally simulate MapReduce and PRAM, by adopting a form of key-value messages. We show a stronger result, which simply uses the message scheme of Section 3, referred to as designated messages in [24].

Theorem 4: MapReduce and PRAM can be optimally simulated by (a) AAP and (b) GRAPE with designated messages only. \(\Box\)

Proof: Since PRAM can be simulated by MapReduce [32], and AAP can simulate GRAPE, it suffices to show that GRAPE can optimally simulate MapReduce with the message scheme of Section 2.

A MapReduce algorithm \(\mathcal{A}\) can be specified as a sequence \((B_1, \ldots, B_k)\) of subroutines, where \(B_r(\in [1, k])\) consists of a mapper \(\mu_r\) and a reducer \(\rho_r\) [20, 32]. To simulate \(\mathcal{A}\) by GRAPE, we give a PIE program \(\rho\) in which (1) PEval is the mapper \(\mu_1\) of \(B_1\), and (2) IncEval simulates reducer \(\rho_1\) and mapper \(\mu_{i+1}\) \((i \in [1, k - 1])\), and reducer \(\rho_k\) in the final round. We define IncEval that treats the subroutines \(B_1, \ldots, B_k\) of \(\mathcal{A}\) as program branches. Assume that \(\mathcal{A}\) uses \(n\) processors. We add a clique \(G_W\) of \(n\) nodes as input, one for each worker, such that any two workers can exchange data stored in the status variables of their border nodes in \(G_W\). We show that \(\rho\) incurs no more cost than \(\mathcal{A}\) in each step, using \(n\) processors. \(\Box\)

5 PROGRAMMING WITH AAP

We have seen how AAP parallelizes CC (Examples 2–4). We next examine two PIE algorithms given in [24], including SSSP and CF. We also give a PIE program for PageRank. As opposed to [24], we parallelize these algorithms in Sections 5.1–5.3 under AAP. These show that AAP does not make programming harder.

5.1 Graph Traversal

We start with the single source shortest path problem (SSSP). Consider a directed graph \(\mathcal{G} = (V, E, L)\) in which for each edge \(e\), \(L(e)\) is a positive number. The length of a path \((v_0, \ldots, v_k)\) in \(G\) is the sum of \(L(v_{i-1}, v_i)\) for \(i \in [1, k]\). For a pair \((s, v)\) of nodes, denote by \(\text{dist}(s, v)\) the shortest distance from \(s\) to \(v\). SSSP is stated as follows.

- Input: A directed graph \(G\) as above, and a node \(s\) in \(G\).
- Output: Distance \(\text{dist}(s, v)\) for all nodes \(v\) in \(G\).

AAP parallelizes SSSP in the same way as GRAPE [24].

(1) PIE. AAP takes Dijkstra’s algorithm [25] for SSSP as PEval and the sequential incremental algorithm developed in [42] as IncEval. It declares a status variable \(x_{v}\) for every node \(v\), denoting \(\text{dist}(s, v)\), initially \(\infty\) except \(\text{dist}(s, s) = 0\). The candidate set \(C_t\) at each \(F_i\) is \(F_i, O\). The status variables in the candidates set are updated by PEval and IncEval as in [24], and aggregated by using min as \(f_{agg}\). When no changes are incurred to these status variables, Assemble is invoked to take the union of all partial results.
(2) Correctness is assured by the correctness of the sequential algorithms for SSSP and Theorem 2. To see this, define order ≤ on sets $S_1$ and $S_2$ of nodes in the same fragment $F_1$ such that $S_1 \leq S_2$ if for each node $v \in F_1$, $v_1 \cdot \text{dist} \leq v_2 \cdot \text{dist}$, where $v_1$ and $v_2$ denote the copies of $v$ in $S_1$ and $S_2$, respectively. Then by the use of min as aggregate $f_{agg}$, IncEval is both contracting and monotonic.

5.2 Collaborative Filtering

We next consider collaborative filtering (CF) [36]. It takes as input a bipartite graph $G$ that includes two types of nodes, namely, users $U$ and products $P$, and a set of weighted edges $E \subseteq U \times P$. More specifically, (1) each user $u \in U$ (resp. product $p \in P$) carries an (unknown) latent factor vector $u \cdot f$ (resp. $p \cdot f$). (2) Each edge $e = (u, p)$ in $E$ carries a weight $r(e)$, estimated as $u \cdot f^T \cdot p \cdot f$ (possibly 0, i.e., “unknown”) that encodes a rating from user $u$ to product $p$. The training set $E_T$ refers to edge set $\{e \in E \mid r(e) \neq 0\}$, i.e., all the known ratings. The CF problem is stated as follows.

- **Input:** A directed bipartite graph $G$, and a training set $E_T$.
- **Output:** The missing ratings. The CF problem is stated as follows.

  - **Output:** The PageRank scores of nodes in $G$.

AAP parallelizes PageRank along the same lines as [47, 57].

(1) ** PIE.** PEval declares a status variable $x_u$ for each node $u \in F_1$ to keep track of updates to $v$ from other nodes in $F_1$. It takes $F_1, O$ as its candidate set $C_i$. Starting from an initial score 0 and an update $x_u$, (initially $1 - d$) for each $v$, PEval (a) increases the score $P_v$ by $x_u$, and (b) updates the variable $x_u$ for each $u$ linked from $v$ by an incremental change $d \times x_u / N_v$. At the end of its process, it sends the values of $C_i \cdot x$ to its neighboring workers.

Upon receiving messages, IncEval iteratively updates scores. It (a) first aggregates changes to each border node from other workers by using sum as $f_{agg}$; (b) it then propagates the changes to update other nodes in the local fragment by carrying out the same computation as in PEval; and (c) it derives the changes to the values of $C_i \cdot x$ and sends them to its neighboring workers.

Assemble collects the scores of all the nodes in $G$ when the sum of changes of two consecutive iterations at each worker is below $\epsilon$.

(2) Correctness. We show that the PIE program under AAP terminates and has the Church-Rosser property, along the same lines as the proof of Theorem 2. The proof makes use of the following property, as also observed by [57]; for each node $v$ in graph $G$, $P_v$ can be expressed as $\sum_{v \in P} p(v) + (1 - d)$, where $P$ is the set of all paths to $v$ in $G$, $P$ is a path $(v_0, v_1, \ldots, v_n, v)$, $P(v) = (1 - d) \cdot \prod_{j=1}^{n} \frac{d}{N_j}$, and $N_j$ is the out-degree node $v_j$ for $j \in [1, n]$.

Remark. Bounded staleness forbids fastest workers to outpace the slowest ones by more than $\epsilon$ steps. It is mainly to ensure the correctness and convergence of CF [30, 53]. By Theorem 2, CC and SSSP are not constrained by bounded staleness; conditions T1, T2 and T3 suffice to guarantee their convergence and correctness. Hence fast workers can move ahead any number of rounds without affecting their correctness and convergence. One can show that PageRank does not need bounded staleness either, since for each path $p \in P$, $p(v)$ can be added to $P_v$ at most once (see above).

6 IMPLEMENTATION OF GRAPE+

As proof of concept, we have implemented GRAPE+ starting from scratch, in C++ with 17000 lines of code.

The architecture of GRAPE+ is shown in Fig. 5, to extend GRAPE by supporting AAP. Its top layer provides interfaces for developers to register their PIE programs, and for end users to run registered PIE programs. The core of GRAPE+ is its engine, to generate parallel evaluation plans. It schedules workload for working threads to carry out the evaluation plans. Underlying the engine are several components, including (1) an MPI controller [5] to handle message...
We evaluated GRAPE+ outperform the other systems. Indeed, Table 1 shows the performance of SSSP and PageRank of the systems with 192 workers; results on the other algorithms are consistent. Hence we only report the performance of these four systems in details. In all the experiments we also evaluated GRAPE+BSP, GRAPE+AP and GRAPE+SSP. Note that GRAPE [24] is essentially GRAPE+BSP.

Experimental setting. We used real-life and synthetic graphs. Graphs. We used five real-life graphs of different types, such that each algorithm was evaluated with two real-life graphs. These include (1) Friendster [1], a social network with 65 million users and 1.8 billion links; we randomly assigned weights to test SSSP; (2) traffic [7], an (undirected) US road network with 23 million nodes (locations) and 58 million edges; (3) UKWeb [8], a Web graph with 133 million nodes and 5 billion edges. We also used two recommendation networks (bi-partite graphs) to evaluate CF, namely, (4) movieLens [4], with 20 million movie ratings (as weighted edges) between 138000 users and 27000 movies; and (5) Netflix [6], with 100 million ratings between 17770 movies and 480000 customers.

To test the scalability of GRAPE+, we developed a generator to produce synthetic graphs $G = (V, E, L)$ controlled by the numbers of nodes $|V|$ (up to 300 million) and edges $|E|$ (up to 10 billion).

The synthetic graphs and, e.g., UKWeb, Friendster, are too large to fit in a single machine. Parallel processing is a must for them.

Queries. For SSSP, we sampled 10 source nodes for each graph $G$ used such that each node has paths to or from at least 90% of the nodes in $G$, and constructed an SSSP query for each of them.

Graph computations. We evaluated SSSP, CC, PageRank and CF over GRAPE+ by using their PIE programs developed in Sections 2 and 5. We used "default" code provided by the competitor systems when it is available. Otherwise we made our best efforts to develop "optimal" algorithms for them, e.g., CF for PowerSwitch.

We used XtraPuLP [46] as the default graph partition strategy. To evaluate the impact of stragglers, we randomly reshuffled a small portion of each partitioned input graph when conducting the evaluation, and made the graphs skewed.

We deployed the systems on an HPC cluster. For each experiment, we used up to 20 servers, each with 16 threads of 2.40GHz, and 128GB memory. On each thread, a GRAPE+ worker is deployed. We ran each experiment 5 times. The average is reported here.

Experimental results. We next report our findings.

Exp-1: Efficiency. We first evaluated the efficiency of GRAPE+ by varying the number $n$ of workers used, from 64 to 192. We evaluated (a) SSSP and CC with real-life graphs traffic and Friendster; (b) PageRank with Friendster and UKWeb, and (c) CF with movieLens and Netflix, based on applications of these algorithms in transportation networks, social networks, Web rating and recommendation.

(1) SSSP. Figures 6(a) and 6(b) report the performance of SSSP.

(a) GRAPE+ consistently outperforms these systems in all cases. Over traffic (resp. Friendster) and with 192 workers, it is on average 1673 (resp. 3.0) times, 1085 (resp. 15) times and 1270 (resp. 2.56) times faster than synchronized GraphLab_sync, asynchronized GraphLab_async and hybrid PowerSwitch, respectively.

7 EXPERIMENTAL STUDY

Using real-life and synthetic graphs, we conducted four sets of experiments to evaluate the (1) efficiency, (2) communication cost, and (3) scale-up of GRAPE+, and (4) the effectiveness of AAP and the impact of graph partitioning strategies on its performance. We also report a case study in Appendix B to illustrate how dynamic adjustment of AAP works. We compared the performance of GRAPE+ with (a) Giraph [2] and synchronized GraphLab_sync [26] under BSP, (b) asynchronous GraphLab_async, GiraphUC [28] and Maiter [57] under AP, (c) Petuum [53] under SSP, (d) PowerSwitch [52] under HSync, and (e) GRAPE+ simulations of BSP, AP and SSP, denoted by GRAPE+BSP, GRAPE+AP, GRAPE+SSP, respectively.

We find that GraphLab_async, GraphLab_sync, PowerSwitch and GRAPE+ outperform the other systems. Indeed, Table 1 shows the performance of SSSP and PageRank of the systems with 192 workers; results on the other algorithms are consistent. Hence we only report the performance of these four systems in details. In all the experiments we also evaluated GRAPE+BSP, GRAPE+AP and GRAPE+SSP. Note that GRAPE [24] is essentially GRAPE+BSP.

Experimental setting. We used real-life and synthetic graphs. Graphs. We used five real-life graphs of different types, such that each algorithm was evaluated with two real-life graphs. These include (1) Friendster [1], a social network with 65 million users and 1.8 billion links; we randomly assigned weights to test SSSP; (2) traffic [7], an (undirected) US road network with 23 million nodes (locations) and 58 million edges; (3) UKWeb [8], a Web graph with 133 million nodes and 5 billion edges. We also used two recommendation networks (bi-partite graphs) to evaluate CF, namely, (4) movieLens [4], with 20 million movie ratings (as weighted edges) between 138000 users and 27000 movies; and (5) Netflix [6], with 100 million ratings between 17770 movies and 480000 customers.

To test the scalability of GRAPE+, we developed a generator to produce synthetic graphs $G = (V, E, L)$ controlled by the numbers of nodes $|V|$ (up to 300 million) and edges $|E|$ (up to 10 billion).

The synthetic graphs and, e.g., UKWeb, Friendster, are too large to fit in a single machine. Parallel processing is a must for them.

Queries. For SSSP, we sampled 10 source nodes for each graph $G$ used such that each node has paths to or from at least 90% of the nodes in $G$, and constructed an SSSP query for each of them.

Graph computations. We evaluated SSSP, CC, PageRank and CF over GRAPE+ by using their PIE programs developed in Sections 2 and 5. We used "default" code provided by the competitor systems when it is available. Otherwise we made our best efforts to develop "optimal" algorithms for them, e.g., CF for PowerSwitch.

We used XtraPuLP [46] as the default graph partition strategy. To evaluate the impact of stragglers, we randomly reshuffled a small portion of each partitioned input graph when conducting the evaluation, and made the graphs skewed.

We deployed the systems on an HPC cluster. For each experiment, we used up to 20 servers, each with 16 threads of 2.40GHz, and 128GB memory. On each thread, a GRAPE+ worker is deployed. We ran each experiment 5 times. The average is reported here.

Experimental results. We next report our findings.

Exp-1: Efficiency. We first evaluated the efficiency of GRAPE+ by varying the number $n$ of workers used, from 64 to 192. We evaluated (a) SSSP and CC with real-life graphs traffic and Friendster; (b) PageRank with Friendster and UKWeb, and (c) CF with movieLens and Netflix, based on applications of these algorithms in transportation networks, social networks, Web rating and recommendation.

(1) SSSP. Figures 6(a) and 6(b) report the performance of SSSP.

(a) GRAPE+ consistently outperforms these systems in all cases. Over traffic (resp. Friendster) and with 192 workers, it is on average 1673 (resp. 3.0) times, 1085 (resp. 15) times and 1270 (resp. 2.56) times faster than synchronized GraphLab_sync, asynchronized GraphLab_async and hybrid PowerSwitch, respectively.
The performance gain of GRAPE+ comes from the following: (i) efficient resource utilization by dynamically adjusting relative progress of workers under AAP; (ii) reduction of redundant computation and communication by the use of incremental IncEval; and (iii) optimization inherited from strategies for sequential algorithms. Note that under BSP, AP and SSP, GRAPE+BS, GRAPE+AP and GRAPE+SSP can still benefit from (ii) and (iii).

As an example, GraphLab_sync took 34 (resp. 10749) rounds over Friendster (resp. traffic), while by using IncEval, GRAPE+BS and GRAPE+SSP took 21 and 30 (resp. 31 and 42) rounds, respectively, and hence reduced synchronization barriers and communication costs. In addition, GRAPE+ inherits the optimization techniques from sequential (Dijkstra) algorithm by employing priority queues to prioritize vertex processing; in contrast, this optimization strategy is beyond the capacity of the vertex-centric systems.

(b) GRAPE+ is on average 2.42, 1.71, and 1.47 (resp. 2.45, 1.76, and 1.40) times faster than GRAPE+BS, GRAPE+AP and GRAPE+SSP over traffic (resp. Friendster), up to 2.69, 1.97 and 1.86 times, respectively. Since GRAPE+, GRAPE+BS, GRAPE+AP and GRAPE+SSP are the same system under different modes, the gap reflects the effectiveness of different models. We find that the idle waiting time of AAP is 32.3% and 55.6% of that of BSP and SSP, respectively. Moreover, when measuring stale computation in terms of the total extra computation and communication time over BSP, the stale computation of AAP accounts for 37.2% and 47.1% of that of AP and SSP, respectively. These verify the effectiveness of AAP by dynamically adjusting relative progress of different workers.

(c) GRAPE+ takes less time when $n$ increases. It is on average 2.49 and 2.25 times faster on traffic and Friendster, respectively, when $n$ varies from 64 to 192. That is, AAP makes effective use of parallelism by reducing stragglers and redundant stale computations.

(2) CC. As reported in Figures 6(c) and 6(d) over traffic and Friendster, respectively, (a) GRAPE+ outperforms GraphLab_sync, GraphLab_async and PowerSwitch. When $n = 192$, GRAPE+ is on average 313, 93 and 51 times faster than the three systems, respectively. (b) GRAPE+ is faster than its variants under BSP, AP and SSP, on average by 20.87, 1.34 and 3.36 (resp. 3.21, 1.11 and 1.61) times faster over traffic (resp. Friendster), respectively, up to 27.4, 1.39 and 5.04 times. (c) GRAPE+ scales well with the number of workers used: it is on average 2.68 times faster when $n$ varies from 64 to 192.

(3) PageRank. As shown in Figures 6(e)-6(f) over Friendster and UKWeb, respectively, when $n = 192$, (a) GRAPE+ is on average 5, 9 and 5 times faster than GraphLab_sync, GraphLab_async and PowerSwitch, respectively. (b) GRAPE+ outperforms GRAPE+BS, GRAPE+AP and GRAPE+SSP by 1.80, 1.90 and 1.25 times, respectively, up to 2.50, 2.16 and 1.57 times. This is because GRAPE+ reduces stale computations, especially those of stragglers. On average, stragglers took 50, 27 and 28 rounds under BSP, AP and SSP, respectively, as opposed to 24 rounds under AAP. (d) GRAPE+ is on average 2.16 times faster when $n$ varies from 64 to 192.

(4) CF. We used movieLens [4] and Netflix with training set $|E_t| = 90\%|E|$, as shown in Figures 6(g)-6(h), respectively. On average (a) GRAPE+ is 11.9, 9.5, 10.0 times faster than GraphLab_sync, GraphLab_async and PowerSwitch, respectively. (b) GRAPE+ beats GRAPE+BS, GRAPE+AP and GRAPE+SSP by 1.38, 1.80 and 1.26 times faster than GraphLab_sync, GraphLab_async and PowerSwitch, respectively. (c) GRAPE+ takes less time when $n$ increases. It is on average 2.49 and 2.25 times faster on traffic and Friendster, respectively, when $n$ varies from 64 to 192. That is, AAP makes effective use of parallelism by reducing stragglers and redundant stale computations.

Figure 6: Performance Evaluation
times, up to 1.67, 3.16 and 1.38 times, respectively. (c) GRAPE+ is on average 2.3 times faster when $n$ varies from 64 to 192.

Single-thread. Among the graphs traffic, movieLens and Netflix can fit in a single machine. On a single machine, it takes 6.7s, 4.3s and 2354.5s for SSSP and CC over traffic, and CF over Netflix, respectively. Using 64-192 workers, GRAPE+ is on average from 1.63 to 5.2, 1.64 to 14.3, and 4.4 to 12.9 times faster than single-thread, depending on how heavy stragglers are. Observe the following. (a) GRAPE+ incurs extra overhead of parallel computation not experienced by a single machine, just like other parallel systems. (b) Large graphs such as UKWeb are beyond the capacity of a single machine, and parallel computation is a must for such graphs.

Exp-2: Communication. Following [29], we tracked the total bytes sent by each machine during a run, by monitoring the system file /proc/net/dev. The communication costs of PageRank and SSSP over Friendster are reported in Table 1, when 192 workers were used. The results on other algorithms are consistent and hence not shown. These results tell us the following.

(1) On average GRAPE+ ships 22.4%, 8.0% and 68.3% of data shipped by GraphLab sync, GraphLab async and PowerSwitch, respectively. This is because GRAPE+ (a) reduces redundant stale computations and hence unnecessary data traffic, and (b) ships only changed values of update parameters by incremental IncEval.

(2) The communication cost of GRAPE+ is 1.22X, 40% and 1.02X compared to that of GRAPE+ BSP, GRAPE+ AP and GRAPE+ SSSP, respectively. Since AAP allows workers with small workload to run faster and have more iterations, the amount of messages may increase. Moreover, workers under AAP additionally exchange their states and statistics to adjust relative speed. Despite these, its communication cost is not much worse than that of BSP and SSSP.

Exp-3: Scale-up of GRAPE+. As observed in [41], the speed-up of a system may degrade when using more workers. Thus we evaluated the scale-up of GRAPE+, which measures the ability to keep similar performance when both the size of graph $G = (|V|, |E|)$ and the number $n$ of workers increase proportionally. We varied $n$ from 96 to 320, and for each $n$, deployed GRAPE+ over a synthetic graph of size varied from (60M, 2B) to (300M, 10B), proportional to $n$.

As reported in Figures 6(i) and 6(j) for SSSP and PageRank, respectively, GRAPE+ preserves a reasonable scale-up. That is, the overhead of AAP does not weaken the benefit of parallel computation. Despite the overhead for adjusting relative progress, GRAPE+ retains scale-up comparable to that of BSP, AP and SSSP.

The results on other algorithms are consistent (not shown).

Exp-4: Effectiveness of AAP. To further evaluate the effectiveness of AAP, we tested (a) the impact of graph partitioning on AAP, and (b) the performance of AAP over larger graphs with more workers. We evaluated GRAPE+, GRAPE+ BSP, GRAPE+ AP and GRAPE+ SSSP. We remark that these are the same system under different modes, and hence the results are not affected by implementation.

Impact of graph partitioning. Define $r = \frac{\|F_{\text{max}}\|}{\|F_{\text{median}}\|}$, where $\|F_{\text{max}}\|$ and $\|F_{\text{median}}\|$ denote the size of the largest fragment and the median size, respectively, indicating the skewness of a partition.

As shown in Fig. 6(k) for SSSP over Friendster, in which the x axis is $r$, (a) different partitions have an impact on the performance of GRAPE+, just like on other parallel graph systems. (b) The more skewed the partition is, the more effective AAP is. Indeed, AAP is more effective with larger $r$. When $r = 9$, AAP outperforms BSP, AP, SSSP by 9.5, 2.3, and 4.9 times, respectively. For a well-balanced partition ($r = 1$), BSP works well since the chances of having stragglers are small. In this case AAP works as well as BSP.

AAP in a large-scale setting. We tested synthetic graphs with 300 million vertices and 10 billion edges, generated by GTgraph [3] following the power law and the small world property. We used a cluster of up to 320 workers. As shown in Fig. 6(l) for PageRank, AAP is on average 4.3, 14.7 and 4.7 times faster than BSP, AP and SSSP, respectively, up to 5.0, 16.8 and 5.9 times with 320 workers. Compared to the results in Exp-1, these show that AAP is far more effective on larger graphs with more workers, a setting closer to real-life applications, in which stragglers and stale computations are often heavy. These further verify the effectiveness of AAP.

The results on other algorithms are consistent (not shown).

Summary. We find the following. (1) GRAPE+ consistently outperforms the state-of-the-art systems. Over real-life graphs and with 192 workers, GRAPE+ is on average (a) 2080, 838, 530, 728, 1850 and 636 times faster than Giraph, GraphLab sync, GraphLab async, GiraphUC, Maiter and PowerSwitch for SSSP, (b) 835, 314, 93 and 368 times faster than Giraph, GraphLab sync, GraphLab async and GiraphUC for CC, (c) 339, 4.8, 8.6, 346, 9.7 and 4.6 times faster than Giraph, GraphLab sync, GraphLab async and GiraphUC, Maiter and PowerSwitch for PageRank, and (d) 11.9, 9.5 and 30.9 times faster than GraphLab sync, GraphLab async and Petuum for CF, respectively. Among these PowerSwitch has the closest performance to GRAPE+. (2) It incurs as small as 0.0001%, 0.027%, 0.13% and 57.7% of the communication cost of these systems for these problems, respectively. (3) AAP effectively reduces stragglers and redundant stale computations. It is on average 4.8, 1.7 and 1.8 times faster than BSP, AP and SSSP for these problems over real-life graphs, respectively. On large-scale synthetic graphs, AAP is on average 4.3, 14.7 and 4.7 times faster than BSP, AP and SSSP, respectively, up to 5.0, 16.8 and 5.9 times with 320 workers. (4) The heavier stragglers and stale computations are, or the larger the graphs are and the more workers are used, the more effective AAP is. (5) GRAPE+ scales well with the number $n$ of workers used. It is on average 2.37, 2.68, 2.17 and 2.3 times faster when $n$ varies from 64 to 192 for SSSP, CC, PageRank and CF, respectively. Moreover, it has good scale-up.

8 CONCLUSION

We have proposed AAP to remedy the limitations of BSP and AP by reducing both stragglers and redundant stale computations. As opposed to [54], we have shown that as an asynchronous model, AAP does not make programming harder, and it retains the ease of consistency control and convergence guarantees. We have also developed the first condition to warrant the Church-Rosser property of asynchronous runs, and a simulation result to justify the power and flexibility of AAP. Our experimental results have verified that AAP is promising for large-scale graph computations.

One topic for future work is to improve adjustment function $\delta$ for different computations. Another topic is to handle streaming updates by capitalizing on the capability of incremental IncEval.

APPENDIX A: PROOFS

Proof of Theorem 1

It is easy to verify that if $\rho$ terminates at ($N_\pi+1$)-th round under AAP for each fragment $F_i$ ($i \in [1,n]$), then in each round $r \leq N_\pi$ IncEval changes at least one update parameter. Using this property, we show that under conditions T1 and T2, $\rho$ always terminates under AAP. Assume by contradiction that there exist a query $Q \in Q$ and a graph $G$ such that $\rho$ does not terminate. Denote by (a) $N_\pi$ the size of the finite set consisting of assigned values for variable $x$, where $x$ is an update parameter of $G$; and (b) $N = \sum_{x \in \mathcal{X}} I_x \in [1,m] N_x$, i.e., the total number of distinct values assigned to update parameters. Since $\rho$ does not terminate, there exists a worker $P_i$ running at least $N + 1$ times in the trace of AAP. By the property above, in each round of IncEval, at least one status variable is updated. Hence there exists a variable $x$ that is updated $N_\pi + 1$ times. Moreover, since IncEval is contracting, the assigned values to $x$ follow a partial order. Thus $x$ has to be assigned $N_\pi + 1$ distinct values, which contradicts to the assumption that there are only $N_\pi$ distinct values for $x$.
Denote by $\bar{R}_i^r$ the partial result on the $i$-th fragment in $\sigma^*$ after $r$ rounds. Then $(\bar{R}_1^r, \ldots, \bar{R}_m^r)$ is a fixpoint of $\rho$ under BSP. To show the Church-Rosser property, we only need to show that an arbitrary run $\sigma$ of $\rho$ under AAP converges to the same fixpoint as $\sigma^*$. More specifically, assume that worker $P_i$ terminates after $r_i$ rounds at partial result $R_i^{r_i}$ in $\sigma$. Then $(R_1^{r_1}, \ldots, R_m^{r_m}) = (\bar{R}_1^r, \ldots, \bar{R}_m^r)$.

It suffices to prove the following:

1. $R_i^{r_i} \preceq \bar{R}_i^r$ for $i \in [1,m]$ and $r \geq 0$, i.e., partial results in the BSP run $\sigma^*$ are no “smaller” than the fixpoint in the run $\sigma$ (Lemma 5);
2. $R_i^{r_i} \preceq \bar{R}_i^r$ for $i \in [1,m]$ and $r \geq 0$, i.e., the partial results in the run $\sigma$ are no “smaller” than the fixpoint in the run $\sigma^*$ (Lemma 6).

In the sequel, we will pick a run $\sigma$ of $\rho$ under AAP and compare the fixpoint in $\sigma$ and $\sigma^*$ by proving Lemma 5 and Lemma 6.

**Notation.** We first refine the partial order $\preceq$ on partial results $R_i^r$, which includes update parameters $\bar{x}$. The order $\preceq$ implies a partial order $\preceq_P$ on the domain of update parameters. Denote by $S_x$ and $S'_{x_i}$ the multi-sets of values for a parameter $x$. We write $S_x \preceq S_{x'_i}$ if the minimal element in $S_{x'_i}$ is “no larger” than any element in $S_x$ w.r.t. order $\preceq_P$. For example, if $\preceq_P$ is the linear order over integers, $S_x = \{1, 3, 3, 4, 5\}$ and $S_{x'_i} = \{3, 7, 8, 1\}$, then $S_x \preceq S_{x'_i}$ since the minimal element 1 in $S_x$ satisfies the condition. We extend $\preceq$ to collections $\bar{x}_i$. That is, we write $S_{\bar{x}_i} \preceq S_{\bar{x}'_i}$ if $S_{\bar{x}_i} \preceq S_{\bar{x}'_i}$ for each $x_i$.

Let $S$ and $T$ be the collections of updated parameters associated with $R_i^r$ and $R_i^{r_i}$, respectively. Then the order $R_i^{r_i} \preceq R_i^r$ “covers” both the order on the “real” partial results $R_i^r$ and $R_i^{r_i}$, and the order $S \preceq T$ on updated parameters. We restate conditions T2 and T3 as follows.

(T2) If $R_i^{r_i+1} = \text{IncEval}(Q, R_i^r, F_i^r(x_i), M_i)$ and $M_i = \text{fagg}(\bar{x}_i, C_i^r, x_i)$, then $R_i^{r_i+1} \preceq R_i^r$ and $C_i^{r_i+1} \preceq S \preceq T$.

(T3) If $R_i^{r_i} \preceq R_i^r$ and their associated collections of update parameters $S$ and $T$ satisfy $S \preceq T$, then $R_i^{r_i+1} \preceq R_i^{r_i+1}$ and $\text{fagg}(S) \preceq S \preceq T$.

**Lemma 5:** $R_i^{r_i} \preceq R_i^r$ for $i \in [1,m]$ and $r \geq 0$. 

**Proof:** The lemma follows from the following two claims.

**Fixpoint.** In the run $\sigma$, each worker terminates at a fixpoint, i.e., $R_i^r = \text{IncEval}(Q, R_i^r, F_i^r(x_i), M_i)$, where $M_i = \text{fagg}(\emptyset \cup C_i^r, x_i)$. Here the fixpoint means that when the set of messages from other workers is $\emptyset$, $\bar{R}_i^r$ cannot be further improved.

**Consistency.** When all workers terminate, the values of the update parameters are consistent, i.e., for each $i, j \in [1,m]$ with $i \neq j$, and for each variable $x$ in $C_i \cap C_j$, $x$ has the same value in $R_i^r$ and $R_j^r$.

Assuming these claims, we show Lemma 5 by induction on $r$.

- **Basis case.** The case $R_i^{r_i} \preceq R_i^0 = \bar{R}_i^r$ follows from T2 and the fact that the first IncEval runs after the same PEval in both $\sigma$ and $\sigma^*$.

- **Inductive step.** Suppose that $R_i^{r_i} \preceq R_i^{r_j}$ for all $i \in [1,m]$, we can show w.l.o.g. that $R_i^{r_i} \preceq R_i^{r_i+1}$ by using the inductive hypothesis and the monotonicity of IncEval. Let $R_i^{r_i+1} = \text{IncEval}(Q, R_i^r, F_i^r(x_i), M_i)$, where $M_i = \text{fagg}(m_1 \cup \ldots \cup m_k \cup C_i^r, x_i)$ (up to $x_i$) and $m_j$ is message from $R_j^r$ for $j \in [1,k]$. By the fixpoint claim, $R_i^{r_i+1} = \text{IncEval}(Q, R_i^r, F_i^r(x_i), M_i)$, where $M_i = \text{fagg}(\emptyset \cup C_i^r, x_i)$, and $P_i$ terminates at round $r_i$. By the inductive hypothesis, $R_i^{r_i} \preceq R_i^r$. It remains to verify the two claims.

**Proof of the Fixpoint Claim.** It suffices to show that when AAP terminates, $C_i^{r_i} \subseteq (\mathbb{B}_x \cup C_i^{r_i-1}, x_i)$ (i ∈ [1, m]), where $\mathbb{B}_x$ consists of the messages received before the last round, and $C_i^{r_i-1} \supseteq \mathbb{B}_x$. We first show that $\text{fagg}(\emptyset \cup C_i^{r_i-1}, x_i) = \text{fagg}(\emptyset \cup C_i^{r_i-1}, x_i) \preceq R_i^{r_i} = \text{IncEval}(Q, R_i^r, F_i^r(x_i), M_i)$ in two steps.

1. We first show that $\text{fagg}(\emptyset \cup C_i^{r_i-1}, x_i) = \text{IncEval}(Q, R_i^r, F_i^r(x_i), M_i)$ in two steps.

2. The three inequalities follow from (a) the contraction of $\text{IncEval}$ (T2), (b) $C_i^{r_i} \subseteq (\mathbb{B}_x \cup C_i^{r_i-1}, x_i)$ and the monotonicity of $\text{IncEval}$ (T3), and (c) T2, respectively. Thus $\text{fagg}(\emptyset \cup C_i^{r_i-1}, x_i) = \bar{R}_i^r$.

We now show that $\text{fagg}(\emptyset \cup C_i^{r_i-1}, x_i)$ is strictly “smaller” than the fixpoint in $R_i^{r_i}$, a contradiction to the assumption that worker $P_i$ terminates after $r_i$ rounds. Let $\bar{v}$ be the value of $x_i$ in $C_i^{r_i-1} \preceq C_i^{r_i}$, and $\bar{v}_p, \ldots, \bar{v}_j$ is the worker sharing $x_i$. Since $x_i$ is updated, $P_i$ sends a message containing $(x_i^*, \bar{v}_i, \bar{v}_j, \ldots, \bar{v}_l, \bar{v}_p)$. Let $\bar{v}$ be the value of $x_i$ on $P_{\ell}$ for $\ell \in [1,k]$ when $P_{\ell}$ processes the message. There are two cases. (i) If some $\bar{v} = \bar{v}_i (i \in [1,k])$ satisfies $\bar{v} \leq \bar{v}^a$, then AAP sends a message containing $(x_i^*, \bar{v}, \bar{v}_i, \bar{v}_j, \ldots, \bar{v}_l, \bar{v}_p)$ to $P_i$.

**Proof of the Consistency Claim.** We show that if $\bar{v}_i^a$ and $\bar{v}_j^a$ are the final values of an update parameter $x_i$ shared by $P_i$ and $P_j$, respectively, then $\bar{v}_i = \bar{v}_j$. Let $\bar{v}_i^a$ and $\bar{v}_j^a$ be the initial values of $x_i$ in $F_i$ and $F_j$, respectively; then $\bar{v}_i^0 = \bar{v}_j^0$. Observe the following.

(a) If $P_i$ and $P_j$ do not update $x_i$ then $\bar{v}_i = \bar{v}_j$.

(b) Otherwise assume w.l.o.g. that $\bar{v}_i \preceq_{SP} \bar{v}_i^a$ and $\bar{v}_j \neq \bar{v}_j^a$. Consider the round updating $x_i$ on $P_i$ by assigning some $\bar{v}_i = \bar{v}_i^a$ to $x_i$. At the end of this round, $(x_i, \bar{v}_i, \bar{v}_j)$ is sent to $P_j$, triggering one round of computation on $P_j$. By the contraction of $\text{IncEval}$, we have that $\bar{v}_i^a \preceq_{SP} \bar{v}_j$. By a similar argument, we can show that $\bar{v}_i \preceq_{SP} \bar{v}_j$. Putting these together we have that $\bar{v}_i = \bar{v}_j$.

**Lemma 6:** $\bar{R}_i^r \preceq \bar{R}_i^r$ for $i \in [1,m]$ and $r \geq 0$.

**Proof:** Since the BSP run $\sigma^*$ is a special run under AAP, by the fixpoint and consistency claims (Lemma 5), we know the following: (a)
The latter can be verified along the same line as Lemma 5.

We prove that $\tilde{R}_j^r \leq R_j^r$ in two steps. (1) We first construct a finite tree $T$ to represent the computation trace of $R_j^r$, where the root of $T$ is $(i, r)$, and nodes of $T$ are in the form of $(j, t)$, indicating the $t$-th round of incEval on the $j$-th fragment. (2) We then show that $\tilde{R}_j^r \leq R_j^r$ for each node $(j, t)$ of $T$. It follows that $\tilde{R}_j^r \leq R_j^r$.

(1) Tree $T$ is constructed top-down from the root $(i, r)$. For a node $(j, t)$ with $t \neq 0$, we define its children based on the $t$-th round of incEval on the $j$-th fragment. Suppose that $R_j^t$ is computed by $R_j^t = \text{incEval}(Q, R_j^{t-1}, P_j^{t-1}[\tilde{x}_j], M_j)$ and $M_j$ is the aggregation result of $m_1, \ldots, m_k$, which are $k$ messages sent from the $j_1$, $\ldots$, $j_k$-th worker after their $t_1$-th, $\ldots$, $t_k$-th round of incEval, respectively. Then we add $k + 1$ pairs $(j, t-1), (j_1, t_1), (j_2, t_2), \ldots, (j_k, t_k)$ as the children of $(j, t)$. Intuitively, the children of $(j, t)$ encode the dependency of $R_j^t$. The construction stops when each path of $T$ reaches a node $(j, t)$ with $t = 0$. Tree $T$ is finite since $(i, r), (j_1, t_1), \ldots, (j_r, r)$ on a path from the root $(i, r), t_1 > t_2 > \cdots > t_r$; and (ii) $T$ is finite branching since each round of incEval only uses finitely many messages.

(2) We show that $\tilde{R}_j^r \leq R_j^r$ for each node $(j, t)$ of $T$ by induction on decreasing $r$. For the basis case when $t = 0$, $\tilde{R}_j^r \leq R_j^r \leq R_j^0$ by the contraction of incEval (T2). For the inductive step, suppose that $(j, t)$ has children $(j, t-1), (j_1, t_1), (j_2, t_2), \ldots, (j_k, t_k)$, and that the inductive hypothesis holds for $(j, t-1), (j_1, t_1), (j_2, t_2), \ldots, (j_k, t_k)$. We show that $\tilde{R}_j^r \leq R_j^r$. Observe that $R_j^r$ is computed by $R_j^r = \text{incEval}(Q, R_j^{r-1}, P_j^{r-1}[\tilde{x}_j], M_j)$, where $M_j = f_{agg}(m_1 \cup \cdots \cup m_k \cup C_j^{r-1}.\tilde{x})$ denotes changes to $x_j$, and $m_1, \ldots, m_k$ are messages from workers $P_{j_1}, \ldots, P_{j_k}$ after their $t_1$-th, $\ldots$, $t_k$-th round of incEval, respectively. Meanwhile, since $\tilde{R}_j^r$ is a fixpoint, $\tilde{R}_j^r = \text{incEval}(Q, R_j^{r-1}, P_j^{r-1}[\tilde{x}_j], M_j')$, where $M_j' = f_{agg}(\emptyset \cup C_j^{r-1}.\tilde{x})$ denotes changes to $x_j$. By the induction hypothesis, $\tilde{R}_j^r \leq R_j^{r-1}$ and $\tilde{R}_j^r \leq R_j^{r-1}_j (t \in [1, k])$. By the monotonicity of incEval (T3), to show that $\tilde{R}_j^r \leq R_j^r$, it suffices to prove that $C_j^{r-1}.\tilde{x} \leq m_1 \cup \cdots \cup m_k \cup C_j^{r-1}.\tilde{x}$.

This completes the proof of Lemma 6 and hence Theorem 2. □

Proof of Theorem 4

Since PRAM can be simulated by MapReduce [32], and AAP can simulate GRAPE (Section 3), it suffices to show that GRAPE can optimally simulate MapReduce with designated messages.

We show that all MapReduce programs with $n$ processors can be optimally simulated by GRAPE with $n$ processors. A MapReduce algorithm $\mathcal{A}$ is defined as follows. Its input is a multi-set $l_0$ of $(\text{key}, \text{value})$ pairs, and operations are a sequence $(B_1, \ldots, B_k)$ of subroutines, where $B_r$ $(r \in [1, k])$ consists of a mapper $\mu_r$ and a reducer $\rho_r$. Given $l_0$, $\mathcal{A}$ iteratively runs $B_r$ $(r \in [1, k])$ as follows [20, 32]. Denote by $l_r$ the output of subroutine $B_r$ $(r \in [1, k])$.

(i) The mapper $\mu_r$ handles each pair $(\text{key}, \text{value})$ in $l_r-1$ one by one, and produces a multi-set $l_r'$ of $(\text{key}, \text{value})$ pairs as output.

(ii) Group pairs in $l_r'$ by the key values, i.e., two pairs are in the same group if and only if they have the same key value. Group $l_r'$ by distinct keys. Let $G_{k_1}, \ldots, G_{k_b}$ be the obtained groups.

(iii) The reducer $\rho_r$ processes the groups $G_{k_l}$ $(l \in [1, b])$ one by one, and generates a multi-set $l_r$ of $(\text{key}, \text{value})$ pairs as output.

(iv) If $r < k$, $\mathcal{A}$ runs the next subroutine $B_{r+1}$ on $l_r$ in the same way as steps (i)-(iii); otherwise, $\mathcal{A}$ outputs $l_k$ and terminates.

Given a MapReduce algorithm $\mathcal{A}$ with $n$ processors, we simulate $\mathcal{A}$ with a PIE program $B$ by GRAPE with $n$ workers. We use PEval to simulate the mapper $\mu_1$ of $B_1$, and (2) incEval simulates reducer $\rho_1$ and mapper $\mu_{i+1} (i \in [1, k-1])$, and reducer $\rho_k$ in final round.

There are two mismatches: (a) $\mathcal{A}$ has a list $(B_1, \ldots, B_k)$ of subroutines, while incEval of GRAPE is a single function; and (b) $\mathcal{A}$ distributes $(\text{key}, \text{value})$ pairs across processors, while workers of GRAPE exchange message via update parameters only.

For (a), incEval treats subroutines $B_1, \ldots, B_k$ of $\mathcal{A}$ as program branches, and uses an index $r (r \in [1, k])$ to select branches. For (b), we construct a complete graph $G_W$ of $n$ nodes as an additional input of $B$, such that each worker $P_i$ is represented by a node $w_i$ for $i \in [1, n]$. Each node $w_i$ has a status variable $x$ to store a multi-set of $(r, \text{key}, \text{value})$ tuples. By using $G_W$, all $n$ nodes become border nodes, and we can simulate the arbitrary shipment of data in $\mathcal{A}$ by storing the data in the update parameters of the workers of GRAPE.

More specifically, consider a multi-set $l_0$ of $(\text{key}, \text{value})$ pairs as input. We distribute these pairs in $l_0$ exactly the same way as $\mathcal{A}$ does; each node $w_i$ of $G_W$ stores the pairs assigned to worker $P_i$.

The PIE program $B$ is specified as follows.

(1) PEval simulates the mapper $\mu_1$ of the subroutine $B_1$ as follows.

(a) Each worker runs the mapper $\mu_1$ of $B_1$ on its local data.

(b) It computes the output $(l_1)'$ of $\mu_1$ and stores it in the update parameters for later supersteps.

(c) For each pair $(\text{key}, \text{value})$ in $(l_1)'$, it includes a tuple $(1, \text{key}, \text{value})$ in an update parameter.

If worker $P_i$ of the reducer $\rho_1$ is to handle the pair $(\text{key}, \text{value})$, PEval adds $(1, \text{key}, \text{value})$ to the update parameter of node $w_i$.

The aggregation function first takes a union of the update parameters of all $w_i (i \in [1, n])$, and then groups the tuples by key.

(2) incEval first extracts the index $r$ from the $(r, \text{key}, \text{value})$ tuples received, and uses $r$ to select the right subroutine, as remarked earlier. incEval then carries out the following operations:

(a) extract a multi-set $(l_r)'$ of $(\text{key}, \text{value})$ pairs from the received messages of $(r, \text{key}, \text{value})$ tuples;

(b) run the reducer $\rho_r$, which is treated as a branch program of incEval, on $(l_r)'$; denote by $l_r$ the output of $\rho_r$;

(c) if $r = k$, then incEval sets the updated parameter to be empty, which terminates $B$; otherwise, incEval runs the mapper $\mu_{r+1}$ on $l_r$, constructs tuples $(r+1, \text{key}, \text{value})$ for each $(\text{key}, \text{value})$ pairs in the output of $\mu_{r+1}$, and distributes update parameters in the same way as PEval.

(3) Assemble takes a union of the partial results from all workers.

It is easy to verify that the PIE program $B$ correctly simulates the MapReduce program $\mathcal{A}$. Moreover, if $\mathcal{A}$ runs in $T$ time and incurs communication cost $C$, then $B$ takes $O(T)$ time and sends $O(C)$ amount of data. Formally, this is verified by induction on $k$ for the number of subroutines $(B_1, \ldots, B_k)$ in $\mathcal{A}$. □
APPENDIX B: MORE EXPERIMENTAL RESULTS

We did two case studies to show how AAP adaptively adjusts delay stretches and reduces response time, with PageRank and CF.

(1) PageRank. Figure 7 shows the timing diagrams of GRAPE+ BSP, GRAPE+ AP, GRAPE+ SSP and GRAPE+ for PageRank over real-life Friendster. Among 32 workers used, P12 is a straggler (colored in blue and green). Stragglers often arise in the presence of streaming updates, even when we start with an evenly partitioned graph.

(a) BSP. As shown in Figure 7(a), the straggler P12 dominated the running time. Each superstep of the BSP run was slowed down by the straggler due to the global synchronization. The other 31 workers mostly idled, and the run took 13 rounds and 174s.

(b) AP. GRAPE+ AP did slightly better and took 166s, as shown in Figure 7(b). Idling was substantially reduced. However, fast workers performed far more rounds of computation than BSP, and most of these are redundant. The cost was still dominated by the straggler P12. Indeed, after a period of time, a fast worker behaved as follows: it moved ahead, became inactive (idle), got activated by messages produced by P12, and so on, until P12 converged.

(c) SSP. Figure 7(c) depicts a run of GRAPE+ SSP with staleness bound c = 5, i.e., fast workers are allowed to outpace the slowest ones by 5 rounds. It did better at the beginning. However, when the fast workers ran out of c steps, there still existed a gap from straggler P12. Then SSP degraded to BSP and fast workers were essentially synchronized with the straggler. The run took 145s.

(d) AAP. Figure 7(d) shows a run of GRAPE+. It dynamically adjusted delay stretch DS1 for each worker Pi by function δ (Section 3). We set predicate S = true since PageRank does not need bounded staleness (Section 5.3), and initial L⊥ = 0 to start with.

AAP adjusted delay stretch DS12 at straggler P12 as follows. (i) Until round 6, function δ kept DS12 = η12 since messages arrived in a near uniform speed before round 6; there was no need to wait for extra messages. (ii) At round 6, DS12 was increased by 63 based on predicted running time t12 of IncEval at P12 and message arrival rate s12, which were estimated by aggregating consecutive executions of IncEval at all workers. As a result, worker P12 was put on hold for 8s to accumulate messages before entering round 7. This effectively reduced redundant computations. Indeed, P12 converged in 8 rounds, and the run of GRAPE+ took 112s.

Observe the following. (i) Starting from round 3 of P12, fast workers were actually grouped together and ran BSP within the group, by adjusting their relative progress; meanwhile this group and straggler P12 were under AP. As opposed the BSP degradation of SSP, this BSP group does not include straggler P12. Workers in the group had similar workload and speed; there was no straggler among them. These workers effectively utilized resources and performed almost optimally. (ii) Straggler P12 was put on hold from round 7 to accumulate messages; this effectively reduced redundant computations and eventually led to less rounds for P12 to converge. (iii) The estimate of t1 and s1 was quite accurate since the speed of IncEval at the same worker did not drastically vary. (iv) If users opt to set L⊥ as, e.g., 31, function δ can start reduce redundant computations early and straggler P12 can find “optimal” stretch DS1 sooner. It is because of this that we allow users to set L⊥ in function δ.

(2) CF. We also analyzed the runs of CF on Netflix with 64 workers. Note that CF requires staleness bound c. We find the following.

(a) BSP. BSP converged in the least rounds (351), but it incurred excessive idleness and was slower than AAP and SSP.

(b) AP. While idleness was nearly zero, AP took the most rounds (4500) and was slower than AAP and SSP, as also noted in [53].

(c) SSP. Tuning c was helpful. However, it is hard to find an optimal c for SSP. We had to run GRAPE+ SSP 50 times to find the optimal c0.

(d) AAP. To enforce bounded staleness, predicate S is defined as false if r = rmax and |rmax − rmin| > c, for c from 2 to 50 in different tests. In the first a few rounds, function δ set delay stretch L1 for each worker P1 as 60% of the number of workers, i.e., P1 waited and accumulated messages from 60% of other workers before the next round. It then adjusted L1 dynamically for each P1.

AAP performed the best among the 4 models. Better yet, AAP is robust and insensitive to c. Given a random c, AAP dynamically adjusted L1 and outperformed SSP even when SSP was provided with the optimal c0 that was manually found after 50 tests.
