Development of a Polyclonal Competitive Enzyme-Linked Immunosorbent Assay for Detection of Antibodies to *Ehrlichia ruminantium*

Keith J. Sumption,† Edith A. Paxton,‡ and Lesley Bell-Sakyi*

Centre for Tropical Veterinary Medicine, University of Edinburgh, Easter Bush, Roslin, Midlothian EH25 9RG, Scotland, United Kingdom

Received 4 March 2003/Returned for modification 1 May 2003/Accepted 27 June 2003

A polyclonal competitive enzyme-linked immunosorbent assay (PC-ELISA) is described for detection of antibodies to *Ehrlichia* (*Cowdria*) *ruminantium* by using a soluble extract of endothelial cell culture-derived *E. ruminantium* as the antigen and biotin-labeled polyclonal goat immunoglobulins as the competitor. For cattle, diagnostic sensitivity and specificity were 86 and 100%, respectively, with a cutoff of 50 PI and 79 and 100% with a cutoff of 70 PI. Cross-reactions with high-titer experimental or field antisera to other *Ehrlichia* and *Anaplasma* species were observed at up to 68 PI in cattle and up to 85 PI in sheep, and therefore to exclude these cross-reactions, cutoffs of 70 PI for bovine serology and 85 PI for small-ruminant serology were selected. Application of the PC-ELISA to bovine field sera from South Africa gave a higher proportion of positive results than application of the murine macrophage immunofluorescent antibody test or indirect ELISA, suggesting a better sensitivity for detection of recovered cattle, and results with bovine field sera from Malawi were consistent with the observed endemic state of heartwater and the level of tick control practiced at the sample sites. Reproducibility was high, with average standard deviations intraplate of 1.2 PI and interplate of 0.6 PI. The test format is simple, and the test is economical to perform and has a level of sensitivity for detection of low-titer positive bovine sera that may prove to be of value in epidemiological studies on heartwater.

Heartwater (*cowdriosis*) is a frequently fatal disease of susceptible domestic ruminants which has significant economic and developmental impact on livestock health and production in areas of sub-Saharan Africa where vector ticks of the genus *Amblyomma* are present. The disease is caused by *Ehrlichia* (formerly *Cowdria*) *ruminantium*, a rickettsial pathogen in the genogroup which includes the monocytotropic species *Ehrlichia canis* and *Ehrlichia chaffeensis* (3), the agents, respectively, of tropical canine pancytopenia, which has a pantropical distribution, and human monocytic choriomeningitis, which has been reported mainly from North America in association with *Amblyomma americanum* ticks. The latter agent also naturally infects deer (16) and goats (2) in the United States, and differentiation of infections by *E. chaffeensis* and *E. ruminantium* would be required if the latter agent entered the United States, for example from Caribbean islands where heartwater occurs (1). Close antigenic relationships exist between these organisms, indicative of multiple shared epitopes on immunodominant antigens (12).

Serodiagnosis of *E. ruminantium* infection in domestic animals and wildlife has utilized a range of immuneassay methods involving reaction to *E. ruminantium* antigens obtained by infection of murine macrophages (5) or caprine neutrophils (17) or in vitro infection of endothelial cells (21). In vitro-infected endothelial cells have been used in immunofluorescent antibody tests (21), in Western blot tests (11, 19), in indirect enzyme-linked immunosorbent assays (ELISAs) (20, 31), and in a competitive ELISA involving a monoclonal antibody reactive with the *E. ruminantium* major antigenic protein MAP1 (14). A common feature of each of these tests is an unacceptable level of analytical or diagnostic specificity, the former evident at the test development stage through false-positive reactions with sera obtained after experimental infection with various *Ehrlichia* species and the latter evident at the test validation or application stage through high frequencies of false positives with sera from tick-exposed ruminants from heartwater-free areas (6, 12, 19). Cross-reactions with other *Ehrlichia* species are assumed to be the main reason for false-positive reactions, since in most cases a high specificity of these tests with sera from non-tick-exposed animals has been demonstrated. However, the inappropriate selection of cutoff values may also have contributed to reduced specificity (22). Improved specificity has been demonstrated with the use of a portion of the *E. ruminantium* *map1* gene expressed as a recombinant peptide (MAP1-B) in an indirect ELISA format (34) and with the use of a baculovirus-expressed MAP1 antigen in combination with a monoclonal antibody in a competitive ELISA format (15).

Although improvement of specificity has been the principal concern in recent heartwater serodiagnostic test development, the lack of sensitivity is an equally if not more important concern for the use of serology in epidemiological studies in...
areas of endemicity (28, 29). An appropriate diagnostic sensitivity is also very important to reduce the proportion of false negatives in import-export screening. The sensitivity of tests for detection of cattle recovered from heartwater appears to be poor, with a decline of antibodies to negative or minimal levels within 3 to 7 months of infection or of removal from tick infestation, respectively, of calves exposed experimentally to or field challenged with E. ruminantium (18, 29). Down-regulation of antibody responses to E. ruminantium antigens was postulated to explain low seropositivity rates detected by MAP1-B ELISA in cattle sera from farms in Zimbabwe where heartwater is endemic (28, 29). In addition, considerable antigenic variation between E. ruminantium isolates has been detected (13, 27), resulting in serological reactions which can be stronger with homologous than with heterologous antigens, an additional factor which may decrease the sensitivity of serodiagnostic tests for heartwater.

In an attempt to overcome sensitivity problems, a simple competitive ELISA (polyclonal competitive ELISA [PC-ELISA]) was developed. The assay utilizes a relatively crude cell culture-derived antigen and competition between antibodies in test sera and in a polyclonal, biotin-labeled competitor. A heterologous competitor and antigen were used in the reactions in an attempt to improve sensitivity for detection of antibodies to diverse E. ruminantium stocks. Polyclonal competition systems have been reported previously (32) and have the potential to improve sensitivity for detection of antibodies in situations where antibodies are present at very low levels in serum and where antibodies to a range of potential antigens may be present. The methods for production of polyclonal competitor antibody, initial PC-ELISA development, and identification of cutoff levels with acceptable specificities are given below.

### MATERIALS AND METHODS

**Sera from animals experimentally infected with E. ruminantium.** Seven Saanen goats, 9 to 12 months of age and reared in Scotland in tick-free conditions, were infected with E. ruminantium blood stabiles by intravenous inoculation and treated with long-acting oxytetracycline on the second day of the febrile reaction (≥40.5°C) to moderate the severity of the infection. Four E. ruminantium isolates were used: Ball 3 (8) and Welgevonden (4) from South Africa, Senegal (10) from Senegal in West Africa, and Gardel (33) from Guadeloupe in the Caribbean. Animals were infected once only, and sera were collected at regular intervals following infection, aliquoted, and stored at −20°C. Goats were kept tick free at the Centre for Tropical Veterinary Medicine under United Kingdom Home Office regulations for animal experimentation throughout the experiment. Sera were assayed by indirect ELISA (31), and high-titer sera were selected for production of the biotinylated competitor immunoglobulins (Ig). Bovine and ovine sera collected after experimental infection with E. ruminantium were supplied by J. Du Plessis, Onderstepoort Veterinary Institute (OVI), and had been collected from animals which had been reared under tick-free conditions in South Africa; sera from 23 calves and 5 sheep preinfection, 10 calves and 10 sheep after experimental infection with six different E. ruminantium isolates, and 19 calves after immunization with the Ball 3 vaccine stock were tested. Postinfection bovine sera were purposely selected to represent a spectrum of levels of antibody response with a bias towards sera with low titers as determined by the mouse macrophage immunofluorescent antibody test (MIFA) (5).

MIFA results were supplied by J. Du Plessis, OVI, from tests performed as previously described in which a reciprocal titer of 20 or higher was considered to indicate positivity (5). Sera collected sequentially over a 26-week period from a calf (no. 456) reared under tick-free conditions and experimentally infected with the Lutale isolate of E. ruminantium (12) were supplied by F. Jongejan, University of Utrecht, Utrecht, The Netherlands.

Sera from animal populations in heartwater-free locations and areas of endemicity. Sera from 110 cattle, 52 sheep, and 25 goats from Scotland (a heartwater-free country) were selected at random from the surplus at a local diagnostic laboratory. Samples originated from a wide range of locations across Scotland and had been collected as part of routine surveillance activities. Sera from adult cattle kept on a ranch in South Africa where heartwater is endemic were supplied by J. Du Plessis, OVI; the sera had been chosen for study since it was considered that the low proportion of sera from these cattle found to be positive by MIFA was not a true reflection of the exposure to E. ruminantium and the level of herd immunity on the ranch. Serum samples from 90 Malawi zebu calves were supplied by A. Soldan, Livestock Disease Evaluation Project, Lilongwe, Malawi. Calves had been born into village herds located close to six dip stations near Lilongwe (31); sera were collected when the animals were 8 to 9 months of age from calves born in May or June 1992.

Sera from animals naturally and experimentally infected with other Ehrlichia and Anaplasma species. Antisera from animals experimentally infected with defined agents or, where these were not available, antisera from naturally infected animals were tested as indicated in Table 1. Sera collected following experimental infection of Ayrshire cattle in Kenya with the agent of bovine petchial fever (Ehrlichia ondiri) (30) were positive by indirect immunofluorescence with Anaplasma phagocytophilum (previously Ehrlichia phagocytophila) (3) antigens and by Western blotting with antigens of granulocytotropic ehrlichiae (35).

Production of biotinylated competitor Ig. Serum Ig were purified from sera collected from goats infected 28 or 35 days previously with Senegal, Ball 3, or Gardel isolates of E. ruminantium as follows. To 2 ml of constantly stirred caprine serum, 0.54 g of ammonium sulfate (Sigma Aldrich, Poole, United Kingdom) was added slowly, and the mixture was stirred continuously at room temperature for 1 h. After centrifugation at 10,000 × g for 10 min at 4°C, the supernatant was discarded and the pellet was resuspended in 400 μl of Milli-Q purified water (Millipore system). Under constant stirring, 0.1 g of ammonium sulfate was added slowly, and the mixture was stirred continuously at room temperature for 1 h. After centrifugation at 10,000 × g for 10 min at 4°C, the supernatant was discarded and a 20-μl aliquot was mixed with 1 μl of Tween 40, 1 μl of polyclonal goat anti-Rhodius protein conjugate, and 1 μl of biotinylated sheep anti-Rhodius IgG followed by incubation at room temperature for 1 h. The sera were absorbed with a 1:10,000 dilution of E. ruminantium Lutale isolate antigens and Western blotted with rabbit anti-E. ruminantium (35).

sulfate was added, and stirring continued for 60 min to reprecipitate Ig. Following further centrifugation as described before, the supernatant was discarded and the pellet was dissolved in 2 ml of Milli-Q water and dialyzed overnight against a 1,000× volume of distilled water in tubing designed to retain proteins of greater than 12 kD (Sigma Aldrich). The dialyzed Ig were stored at −20°C until further use. Protein concentration was determined by the bicinchoninic acid protein assay method (Pierce & Warriner, Chester, United Kingdom) according to the manufacturer’s protocol and Ig for labeling were diluted in 0.1 M bicarbonate buffer (pH 9.0 to 9.2; Sigma Aldrich) to 2 mg/ml. Thereafter, for bio-
tinylation, each milliliter of diluted Ig was mixed with 30 µl of biotinamidocap-
toic acid (ExtrAvidin-peroxidase; Sigma Aldrich) and incubated with constant mixing for 3 h at room temperature, followed by overnight dialysis as described before but at least a 100× volume of phosphate-buffered saline (PBS). Sodium azide (final concentration, 0.05%) was added as a preser-
ivative, and the biotinylated Ig (Btg) was stored at −20°C.

Development of PC-ELISA. Detergent-extracted soluble antigens of *E. rumin-
phinx anti-E. ruminantium (strongly, weakly, and very weakly positive by indirect ELISA) and negative bovine and caprine sera were used to
to the effect of different test serum/Btg ratios on competitor inhibition, with each combination maintaining a final Tween 20 concentration of 0.05%. A ratio that consistently gave large differences in inhibition levels between weakly positive sera and negative control sera, and a high and reproducible level of color reaction with competitor alone, was utilized in subsequent tests. Color development was done with tetramethyl benzidine (TMB) at 0.1 mg/ml in 0.05 M phosphate citrate buffer, with addition of 1 mM EDTA, and 150 mM sodium chloride) and incubated for 2 min at room temperature, followed by rapid passage through a 26-gauge needle and incuba-
tion at 37°C for 30 min. The lysate was then centrifuged at 16,000 × g for 30 min at 4°C to remove insoluble antigen. The soluble antigen extract was stored at

RESULTS

(i) Identification of cutoff values in relation to reactivity of anti-*Ehrlichia* sera. The cutoff value was defined by reference to inhibition levels obtained with the PC-ELISA with a panel of cattle, sheep, and goat sera from a heartwater-free country (Scotland), sera from goats and cattle experimentally infected with *E. ruminantium*, and sera obtained from mammals experimentally and naturally infected with various other *Ehrlichia* species.

Sera from 110 Scottish cattle had inhibition levels between 1 and 34 PI with the PC-ELISA, while Scottish sheep (n = 52) and goat (n = 25) sera had inhibition levels of 1 to 37 and 3 to 38 PI, respectively. In contrast, inhibition levels for sera from goats and cattle experimentally infected with *E. ruminantium* exceeded 40 PI in all cases. For caprine sera collected between 66 and 122 days after experimental *E. ruminantium* infection, inhibition levels were between 94 and 100 PI, irrespective of the *E. ruminantium* isolate used in the infection. Inhibition levels remained above 84 PI for four goats when tested 550 days post-experimental infection, after maintenance of the goats throughout in tick-free conditions. Inhibition levels for sera collected before and after vaccination of 19 cattle with the *B. bovis* vaccine were below 35 PI before immunization and afterwards exceeded 40 PI in all cases; levels for 13 of the postimmunization sera exceeded 70 PI, while the remainder of the sera had values between 42 and 67 PI (Fig. 1). In the calf experimentally infected with *E. ruminantium* (Lutale), the in-
hibition level obtained with the PC-ELISA following seroconversion remained between 90 and 95 PI until week 26 postinfection.

The inhibition levels for antisera raised against other *Ehrlichia* and *Anaplasma* species were then determined and are shown in Table 1. Sera collected from sheep after experimental infection with *A. phagocytophilum* and from cattle after *E. ondii* infection gave inhibition levels within the normal range obtained for heartwater-naïve Scottish sheep and cattle (less than 40 PI). Higher inhibition levels were found with other ruminant infections; maximal values of 72 and 68 PI were obtained for ovine (*Ehrlichia ovina*) and bovine (presumed natural infections with other *Ehrlichia* species from Namibia) sera, respectively. With nonruminant infections, the highest inhibition level (86 PI) was found for a canine serum collected 9 weeks postinfection with *E. canis*; most sera raised against this organism gave lower inhibition levels.

Eight ovine sera from Zimbabwe from animals with presumed natural infections with other *Ehrlichia* species from areas where heartwater is not endemic and from a farm where *Amblyomma* ticks were not present on domestic livestock gave high inhibition levels (between 53 and 85 PI). These sera had been selected to represent high-titer false positives when tested by immunofluorescence and Western blotting (Table 1).

On the basis of these results, application of a cutoff value of 40 PI would result in a diagnostic sensitivity and specificity of 100% for detection of antibodies after experimental *E. ruminantium* infection in previously tick-free cattle and goats. How-
ever, higher cutoff values, of 70 and 85 PI for bovine and small ruminant sera, respectively, would be necessary to avoid false-
itive results due to experimental or natural infections with
other *Ehrlichia* species, with a consequent reduction in sensitivity (see Discussion and Table 2).

(ii) **Time course of antibody detection following experimental caprine infection.** Seroconversion in the seven experimentally infected Saanen goats was detected by PC-ELISA between 8 and 16 days postinfection when a cutoff of 50 PI was used and was only slightly delayed to between 9 and 18 days for the same sera when a cutoff of 70 PI was used. In relation to the onset of the febrile response, sera were first positive at 70 PI or above on the second or third day of fever of $\geq 40.5^\circ C$. Inhibition levels exceeded 90 PI by 20 days postinfection in all animals and remained at this level throughout the period of monitoring (122 days); the inhibition levels obtained for sera collected sequentially from two of the experimentally infected goats are shown in Fig. 2. In a separate study, inhibition levels between 84 and 95 PI were obtained with sera from four goats infected 550 days previously with *E. ruminantium* (Welgevonden). Therefore, of 11 animals sampled for 3 months or longer after recovery, all tested positive with the 70-PI cutoff and 10 of 11 (91%) tested positive with the 85-PI cutoff.

(iii) **Comparison of biotinylated competitor sera raised against different *E. ruminantium* isolates.** Biotinylated anti-*E. ruminantium* Ig prepared from sera of goats infected with two geographically distinct isolates (Ball 3 from South Africa and Gardel from Guadeloupe) were investigated for the detection of infection in goats with *E. ruminantium* isolates of different geographical origins. Test results for the two competitor preparations were compared during the time course of infections with four *E. ruminantium* isolates (Ball 3, Senegal, Welgevonden, and Gardel). With a cutoff for positivity of 70 PI, there was complete agreement between tests in statuses of 176 sera.

(iv) **Reproducibility of the assay.** In the PC-ELISA, the average intraplate standard deviation in PI was 1.2% (range, 0.5-2.0). Therefore, of 11 animals sampled for 3 months or longer after recovery, all tested positive with the 70-PI cutoff and 10 of 11 (91%) tested positive with the 85-PI cutoff.

0.4 to 2.6%) for nine sera. Interplate average standard deviation in PI for the same nine sera tested on four plates was 0.6% (range, 0.1 to 1.4%).

(v) Comparison of PC-ELISA and indirect ELISA for bovine and ovine sera from South Africa. Bovine sera collected pre-infection \((n/1005/23)\) and postrecovery \((n/1005/10)\) from animals experimentally infected with \(E.\ ruminantium\) or postvaccination \((n/1005/19)\) were tested by PC-ELISA and by indirect ELISA \((31)\). The PC-ELISA had a sensitivity and specificity of 100% with the 70-PI cutoff level for detection of infection status in cattle preinfection and after experimental infection. Of the 19 postvaccination sera, 13, 2, and 4 gave inhibition levels of \(<70, 50\) to 70, and \(>50\) PI, respectively. The indirect ELISA detected 50% of the postrecovery and 11% of the postvaccination bovine sera. Ovine sera collected preinfection \((n/1005/5)\) and postrecovery \((n/1005/10)\) from animals experimentally infected with \(E.\ ruminantium\) were tested by PC-ELISA and by indirect ELISA; both tests correctly identified the statuses of all 15 sera.

The two ELISAs were applied to 20 sera with low MIFA-determined titers \((10, 6,\) and 4 sera with titers of \(<20, 20,\) and 80, respectively) from cattle kept under conditions of \(A.\ omroems\) exposure on a ranch in South Africa where heartwater is endemic. Sixteen of the 20 sera (80%) tested positive by PC-ELISA when a cutoff of 70 PI was applied, and this number rose to 18 of 20 if a cutoff of 50 PI was applied, whereas only 10 of these sera were positive by MIFA (titer of 20 or higher) and 12 were positive by indirect ELISA.

(vi) PC-ELISA results for Malawi zebu calves. The frequency distribution of inhibition levels for 90 sera collected from calves 8 to 9 months of age is shown in Fig. 3. A bimodal distribution of values is suggested, consistent with a mixed population of antibody-positive and -negative animals, with a division between the two groups occurring at about 50 PI.

**DISCUSSION**

The lack of sensitivity and specificity of serological tests for detection of acquired immunity to \(E.\ ruminantium\) has for a long period created uncertainty in the interpretation of cross-sectional studies on herd immunity. Since postexposure antibody levels in calves are observed to decline by 3 to 7 months to levels detected as negative by the MIFA \((5)\) or between 8 and 33 weeks to levels detected as negative by the MAP1-B ELISA \((29, 34)\), longitudinal studies on development of herd immunity and endemic stability \((25)\) require testing of animals at intervals of no longer than 2 months in order to detect the timing of seroconversion. Longer intervals should be appropriate for sheep and goats, since their antibody levels appear to be more durable \((5, 34)\). For cattle in particular, a sensitive and specific serological test would greatly simplify the analysis of interventions upon herd exposure to \(E.\ ruminantium\) by enabling cross-sectional studies on higher numbers of animals at ages at which susceptibility of naive animals to infection is expected to be high. The exposure rate in young animals can provide an important basis for identification of appropriate tick-borne disease control measures, such as immunization or altered acaricide application, but to date has rarely been applied to heartwater control because of the unsuitability of serological tests.

The competitive ELISA described in this paper appears to offer some advantages over other tests, in particular a relatively high sensitivity for bovine infections and ease of use. Practical advantages of the format developed include the use of undiluted test and control sera, obviating a pretest dilution step, and the ability to assay sera from different animal species by using the same reagents on the same plate. The sensitivity was at least as good as that of the MIFA for experimentally infected cattle, and with field sera from South Africa, the PC-ELISA resulted in a higher proportion of seropositives than...
the MIFA. The PC-ELISA results for field sera were considered to be consistent with a high observed level of tick exposure and the apparent presence of endemic stability to heartwater, since the South African samples were collected from adult cattle on a ranch where heartwater was known to occur and seroconversion in Malawi was occurring in the majority of calves within the first 12 months of life (31). For determination of test sensitivity, sera from recovered long-term carrier animals are as important as those from recently recovered animals, as animals in areas of endemicity are expected to be exposed to *E. ruminantium* repeatedly from an early age (25). Selection of high-titer sera following experimental infection and booster challenge of goats (22) or immunization with vaccines with oil adjuvants (23) may lead to overestimation of sensitivity in natural situations. Although sera from bovine carriers were not available in the study described here, since the costs of long-term experimental containment of heartwater-infected animals are very high, difficult bovine sera were selected which had very weak positive or negative test statuses as determined by MIFA and caprine sera were collected from animals with infections which had been treated with antibiotics and without booster challenges, conditions which may favor reduced antibody responses.

Published guidelines for validation of immunoassays (9) emphasize that it is important to determine cross-reactivity with antisera to related organisms at an early stage of test development and also that sera used in test validation should closely resemble those from animals to which the test will be applied (9). In the development of the PC-ELISA, the limit of cross-reactivity with antisera raised against other *Ehrlichia* and *Anaplasma* species was determined and false-positive reactions with the PC-ELISA occurred with caprine or ovine sera at up to 85 PI and up to 68 PI with a bovine serum sample. Although these inhibition levels were high, antibody levels induced in cattle and goats by experimental infection with *E. ruminantium* were usually above the limit of cross-reactivity with other *ehrlichiae*. Although the number of sera used in sensitivity and specificity testing was small, those used were selected to represent low levels of antibody to *E. ruminantium* or high levels of cross-reactivity and, it is hoped, would represent the extremes to be anticipated in the application of tests. Since the application of a cutoff level of 85 PI gave a sensitivity for detection of experimental infection in goats of almost 100% and cross-reactions at above 86 PI were not detected, the performance of the PC-ELISA for this species appears to be adequate. For cattle, the 85-PI cutoff would dramatically reduce sensitivity, but since cross-reactions at above 68 PI were not detected, arguments for a cutoff of 70 PI can be advanced since the sensitivity of the test for detection of recent bovine infections was at least 79% at this cutoff level. Suggested interpretations of PC-ELISA results with caprine and bovine sera are given in Table 2. Where there is an overlap in the distribution of high numbers of false-positive *Ehrlichia* reactions and weak-positive *E. ruminantium* antibody levels, interpretation must be cautious. The absence of suitable vectors of *E. ruminantium* in the environment of the animal or group sampled would support a tentative classification as a cross-reaction.

Since the majority of heartwater serology concerns the detection of potentially infected animals in the field as part of studies on tick-borne disease management, it can be argued that high sensitivity is more important than high specificity so that infected or immune animals are detected. It may also be argued that, provided that specificity is not lower than 80%, the interpretation of levels of herd immunity in areas where heartwater is endemic is not unduly complicated since herd immunity levels of 20 to 40% would not be considered to indicate endemic stability whereas herd immunity rates of >80% would do so. The cutoff value applied to the test for each animal species will depend on the information required; a high cutoff would be appropriate for detection of infection in a herd or population, while a lower cutoff would allow detection of most or all infected animals within a group but would produce some false positives. Although lowering the cutoff value for bovine sera from 70 to 50 PI results in a higher sensitivity, with the resultant increase in the proportion of positive sera from field
situations of endemicity (South Africa and Malawi), this can be considered to have limited effect upon the interpretation of the level of herd immunity in each of these situations. The seropositivity rates were consistent with the levels of *Amblyomma* challenge at each location: 80% in cattle in South Africa under heavy exposure to *Amblyomma hebraeum* and 77% in 8- to 9-month-old calves under *Amblyomma variegatum* exposure and relaxed tick control in Malawi, with the 70 PI cutoff applied with the PC-ELISA. The bimodal distribution of PC-ELISA values from the field-exposed cattle in Malawi supports the argument that the majority of immune animals have inhibition levels higher than 70 PI and that levels between 50 and 70 PI may indicate weak positives or possibly cross-reactions with other *Ehrlichia* species, since sera from non-tick-exposed cattle in Scotland had levels of less than 40 PI. Further studies on the sensitivity of the assay for detection of naive and recovered cattle, sheep, and goats in areas where heartwater is endemic and comparison with other recently developed *E. ruminantium* diagnostic assays such as the MAP-1B ELISA (34) will be required to assess the usefulness of the PC-ELISA for field application.

ACKNOWLEDGMENTS

This research was funded by the Department for International Development of the British government.

We gratefully acknowledge the generous assistance of all those who supplied sera and accompanying data, particularly Jan Du Plessis, Frans Jongejan, Jacqueline Dawson, Maria Pennisi, Suman Mahan, and Andrew Soldan. Alan Walker, Cornelis Bekker, and Ivan Morrison are thanked for useful comments on the manuscript.
