Forgetting in Alzheimer’s Disease: Is it fast?
Is it affected by repeated retrieval?

Running title: Forgetting in Alzheimer’s Disease
Abstract

Objectives. Whether people with Alzheimer’s Disease present with accelerated long term forgetting compared to healthy controls is still debated. Typically, accelerated long term forgetting implies testing the same participants repeatedly over several delays. This testing method raises the issue of confounding repetition effects with forgetting rates. We used a novel procedure to disentangle the two effects.

Methods. Four short stories were presented during an initial in-person assessment of 40 patients with Alzheimer’s Disease and 42 age-matched healthy controls. Our aim was for participants to reach a score of 70% correct (9 out of 13 questions) at encoding. If this criterion was not achieved after the first trial, the four stories were presented again (in a different order); participants took the one minute filler task again and were then retested. We repeated this process until participants reached the 70% criterion or to a maximum of four trials. Cued recall memory tests were completed during follow-up telephone call(s) at different delay intervals. Study material was presented only at encoding, then probed with different question sets on all other delays. Each question set tested different sub-parts of the material. The experiment employed a mixed design. Participants were randomly allocated to either a condition without retrieval practice or a condition with retrieval practice. Participants in the condition without retrieval practice were only tested at two delays: post encoding filled delay and at one month. Participants in the condition with retrieval practice were tested at four delays: post encoding filled delay, one day, one week and one month. Our methodological design allowed us to separate the effects of retesting from the effects of delay.

Results. Alzheimer’s Disease patients showed a significant encoding deficit reflected in the higher number of trials required to reach criterion. Using Linear Mixed Models, we found no group by delay interactions between the post encoding filled delay retrieval and one month delays, with Alzheimer’s Disease groups having a similar decline in performance to healthy controls, irrespective of testing condition. Significant condition by delay interactions were found for both groups (Alzheimer’s Disease and healthy controls), with better performance at one month in the condition with retrieval practice.
Conclusions. Our data showed that Alzheimer’s Disease is not characterised by accelerated long term forgetting, patients in our sample forgot at the same rate as healthy controls. Given the additional trials required by Alzheimer’s patients to reach the 70% correct criterion, their memory impairment appears to be one of encoding. Moreover, Alzheimer’s Disease patients benefited from repeated testing to the same extent as healthy controls. Due to our methodological design, we were also able to show that performance improved under repeated testing conditions, even with partial testing (sampling different features from each narrative on every test session/delay) in both healthy controls and Alzheimer’s Disease.

Key words: Accelerated Forgetting, Repeated testing, Alzheimer’s Disease
1. Introduction

Accelerated long-term forgetting (ALF) has been proposed as one of the main reasons for memory deficits in Alzheimer’s Disease (AD) (e.g., Vallet, et al., 2016). However, studies investigating whether AD patients present with ALF or not, have reported conflicting results (see Table 1). It has been suggested that these differences derive from methodological confounds (Geurts, et al., 2015). Table 1 summarises the literature investigating ALF in AD and prodromal syndromes. Half of the fourteen studies we could glean from the literature found normal long-term forgetting patterns compared to those of healthy controls (HC). We identified several factors that could account for this discrepancy in results.

Firstly, although this is not always acknowledged, a possible confounding factor is whether there are ceiling effects in the performance of HC or floor effects in the patient samples. Four out of the fourteen studies listed in Table 1 are marred by floor effects in the clinical sample (Kopelman, 1985 p. 634; Greene et al., 1996, p. 545; Budson et al., 2001, p. 887; Lombardi et al., 2018, p.8) while three are difficult to interpret given the ceiling effect in the control group (Greene, et al., 1996, p. 545; Degenszajn et al., 2001, p.173; Weston et al., 2018, p. 130).

**Table 1. Summary of studies investigating ALF in AD and MCI**
Secondly, many studies failed to equate baseline performance between the clinical and the healthy group, leading to a possible incorrect assessment of the differences in the forgetting rates between the two groups. Greene et al. (1996) evaluated anterograde episodic memory in patients with AD and in HC using immediate and delayed prose recall. They reported that once initial acquisition of new information on the task was equated across groups, patients with AD did not exhibit ALF. Similarly, Kopelman (1985), using the Huppert-Piercy test, found no evidence of ALF at 24h or 7 days delay, after matching initial learning. On the contrary, Carlesimo et al. (1995) did observe ALF in AD patients at 1 hour and 24 hour delays on a line drawing recognition task. Recently, Weston and colleagues (2018) investigating a group of people affected by a gene mutation resulting in a form of presymptomatic autosomal dominant AD found that these people had a performance similar to HC at initial learning and 30-minute recall on a series of tests (word lists, stories, and figure recall). However, when assessed again after a week, people carrying the mutation had forgotten more than the non-carriers. These differences in findings cannot be attributed solely to whether initial performance was equated or not, to the type of material or testing method (recall/recognition). An additional influencing factor in investigating forgetting derives from the fact that repeated testing is inherent in the study of forgetting, but repeated testing comes with several caveats. One would be, as Weston and colleagues (2018) noted, that we cannot control for some participants rehearsing or at least recalling the material between assessments. The authors comment on the difficulties arising with repeated measures and argue for the importance of identifying new methods of assessment. They propose either to embed testing material amongst other unrelated cognitive tests, or to use recognition tests with material that would be difficult to rehearse by participants between test sessions.

Some of the previous studies have discussed the possible implications of repeated testing on patients’ performance (Greene et al., 1996; Weston et al., 2018). However, none has directly investigated the effects of such repetitions, and whether the same material or different material is used on each test session. In an attempt to address the difficulties arising with repeated testing, a number of approaches have been identified (for a review see Elliott et al., 2014). Baddeley et al. (2019) propose to use material that once learned can be used to test the same individual over longer delays, repeatedly, without testing the same information on each occasion. From the review of the 14 studies on ALF in AD, listed in Table 1, the issue of whether or not the same material was retested on each delay emerges as one of the differentiating factors between studies that have reported ALF and those which have not.
Seven of the 14 studies that investigated ALF in AD patients, used different subsets of the initially encoded material on each testing session. These six studies documented forgetting rates in AD and aMCI similar to that of age-matched controls (Kopelman, 1985; Hart, et al., 1987; Hart, et al., 1988; Christensen et al., 1996; Vallet et al., 2016; Lombardi et al., 2018).

Lastly, we agree with Weston and colleagues (2018) in that repeated measures, and more importantly rehearsal raise important methodological issues. Repeated testing of the same material involves (re)learning of that material on each subsequent testing occasion. However, when different subsets of the initially encoded material are tested on each of the following delays, particularly if no feedback is given, relearning is minimised. These two types of testing procedures could lead to large differences in memory performance between individuals with learning deficits and normal groups, with healthy adults benefiting more from the relearning opportunities compared to patients. In a previous study of ours (under review) we have suggested that memory performance benefits from repeated partial testing (testing different subparts of initially taught material) arise as a result of priming, rather than relearning. If this is to be the case, then amnesic patients should benefit to the same extent as HC as a result of repeated partial testing, thus eliminating the difference in forgetting slopes between the two groups. To surmise if repeated testing provides a new learning opportunity, individuals with learning deficits could potentially be mistaken as exhibiting ALF since they benefit from relearning to a lesser extent, compared to healthy individuals. On the other hand, if it represents priming, then patients with amnesia, such as those with AD, should also exhibit relatively preserved long-term memory performance under repeated partial testing, as the act of repetition would serve to strengthen existing representations thus also benefiting AD patients.

In a recent methodological review of ALF studies, Elliot et al. (2014) concluded that several key factors must be considered when assessing longer-term forgetting. Among their recommendations they suggest that when assessing ALF, tests should allow for repeated testing, while avoiding repeated retrieval as much as possible by using distinctive matched tests. Furthermore, standardised tests of ALF should allow for free recall and cued recall testing, or some type of testing with retrieval support. The Crimes Test (Baddeley et al., 2013) meets both these requirements. This prose recall test is composed of four short stories, each based on an incidence of crime that contains five key features (e.g. the crime, the criminal, the location). It does not demand excessive (initial) learning time and allows for
different subsamples of questions to be tested via cued recall after a range of delays. In a later study, Baddeley et al. (2019) ran two experiments each comprising a repeated testing condition (testing on: immediate, 24 h, one week and one month) and a condition involving a single test after one month. They found that both the Crimes test and a visual test showed clear evidence of forgetting in the single test condition but little evidence of forgetting in the repeated testing condition. The authors suggested that the testing of individual features (subsamples of questions) enabled participants to remember the entire episode which then acted as a further reminder. This lack of forgetting in healthy individuals could provide an ideal test of ALF by avoiding the danger of floor effects (Baddeley et al., 2019). In the current study, we have addressed the question of whether or not ALF does characterise the memory deficits of AD patients using the procedures devised by Baddeley et al. (2019) and designed material closely following The Crimes Test (Baddeley et al., 2013).

We have also addressed a second question, namely whether the performance of AD patients is enhanced by repeated testing. Several studies have shown the advantage of repeated testing on memory performance (Carpenter et al., 2007; Pilotti et al., 2009; Thomas et al., 2018; Baddeley et al., 2019). This enhancement in performance due to retesting, referred to as the testing effect, has been shown in applied situations, including educational settings (e.g., Roediger and Butler, 2011), in healthy older adults (e.g., Ferrer et al., 2004; Baddeley et al., 2019), and to some extent in individuals with memory impairments (e.g., Yan and Dick, 2006; Duff et al., 2008). While the testing effect emerges when tests probe the entire encoded material, when evaluating the effect of partial testing (probing subparts of that material) different viewpoints emerge on how this influences final memory performance. Some suggest that the benefits that arise as a result of partial testing apply only to material that can be integrated, or reconstructed by participants (e.g. prose, video as opposed to individual words, or pictures). However none of the studies which directly address partial testing effects have investigated these issues in clinical samples. A detailed review of the literature investigating partial testing in healthy samples is beyond the scope of the present article (for a discussion see: e.g. Baddeley et al., 2019; Chan et al., 2015; Chan, 2009)

Some indirect evidence suggesting that repeated testing would prove beneficial to AD patients comes from reports which have shown that increasing the delays between testing when recalling information repeatedly (spaced retrieval) can improve memory performance for dementia patients and amnesiacs (e.g., Cull et al., 1996; Brush and Camp, 1998).
Recalling information repeatedly has been shown to improve AD patients’ performance on: object–location associations (Camp and Stevens, 1990), names of different objects (Abrahams and Camp, 1993) and prospective memory tasks (Camp et al., 1996). For example, Kinsella and colleagues (2007) investigated the benefits of spaced retrieval for improving prospective memory performance in patients with early AD compared to healthy older adults and found that the performance of most AD patients improved as a result of spaced-retrieval (combined with elaborated encoding of the task). However, experiments aiming at studying retrieval practice in dementia patients have generally focused on simple cognitive tasks such as face-name associations, object-name or object-location associations, and cue-behaviour associations (see Creighton et al., 2013). The current experiment looks at a more complex task, remembering associations between multiple features within stories.

2. Method
2.1. Participants
2.1.1. Patient sample
The patients were recruited from various geriatric institutions in Bucharest (Romania). Participants’ eligibility for the AD group was restricted to patients with a diagnosis of probable AD, confirmed at 6 months follow-up, based on international diagnostic criteria (NINCDS-ADRDA: McKhann et al., 1984; DSM-IV-TR: American Psychiatric Association, 2000). Patients included in the study should have a Mini-Mental State Examination (MMSE) score between 26-18. They were assessed with a range of standard memory and global cognition tests (see Table 2) and with a paper version of the Temporary Memory Binding test (Della Sala et al., 2018) by the experimenter (first author). Patients also underwent blood screening tests to exclude other potential causes of dementia, all had CT scans, and a few had MRI scans as well. Patients were excluded from the study if they had a past history of stroke, brain traumatic injury, clinical depression or alcoholism. Due to the nature of the testing material, individuals with major hearing impairments were also excluded. Written consent from all patients, or their caregivers was obtained according to the Declaration of Helsinki, as was ethical approval from the relevant ethics committees of each institution involved (Institutul National de Gerontologie si Geriatrie “Ana Aslan” București; Spitalul Universitar de Urgenta ELIAS Sectia Geriatrie Gerontologie Bucuresti; Clinica Pro-memoria Bucuresti).

Table 2. **AD patients’ performance on the background Neuropsychological test battery.**
AD: Alzheimer’s disease; DS: Digit Span (Blackburn, Benton, and Shaffer, 1957); ADL: Activities of Daily Living (Katz, 1983); IADL: Instrumental Activities of Daily Living (Lawton, and Brody, 1969); CDT: Clock Drawing (Shulman, 2000); GDS: The Geriatric Depression Scale (Yesavage, et al., 1983); MoCA: Montreal Cognitive Assessment (Nasreddine et al., 2005); TMB: Temporary Memory Binding test (Della Sala, Kozlova, Stamate, and Parra, 2018).

2. 1.2. Healthy controls
The healthy control (HC) sample was recruited in Romania from GP surgeries and from the local communities. The GPs provided a list of older individuals who were registered with their practice whose medical files showed they were in good health. In Romania, GPs perform regular general examinations of their patients, including cognitive assessment. All the participants included in the study were healthy at the time of testing. Exclusion criteria for the HC were: the absence of psychiatric or neurological conditions, including alcohol or drug abuse or head trauma and a MMSE score higher than 28. This latter criterion was documented by GP records. Written consent from all participants was obtained.

2. 1.3. Comparison between groups
The initial sample included 40 patients with AD (seven men and 33 women) and 44 HC (10 men and 32 women). The HC participants were recruited to match AD patients on age, educational level and when possible gender. The AD participants ranged in age from 55 to 93 years with a mean age of 77.4 years (S.D.=8.4 years) while HC ranged in age from 56 to 89 years with a mean age of 75.6 years (S.D.=8.2 years), there was no statistically significant difference between AD and HC on age (t=-.990; p=.326). The AD participants ranged from 4 to 16 years with a mean of 12.7 (SD=3.7) on level of education, and the HC ranged from 7 to 18 years with a mean of 13.5 (SD=2.8). There was no statistically significant difference between AD and HC on level of education (t=-.988; p=.326).

The final sample included 33 AD patients and 42 HC. Four participants refused to take part on following testing delays (two patients and two controls); one patient had a cerebral stroke between the one week and one month testing delay; the performance of one patient in the condition without retrieval practice was excluded as flagged as a significant outlier and 7 patients were not included in the final analysis as they did not reach the 70% encoding criterion.

Table 3 details the demographics of the subgroups (AD & HC) according to experimental conditions.

2.2. Design
All testing was conducted in Romanian, all neuropsychological tests which were carried out had translated and validated Romanian versions. With regard to the Fables test, even though we initially devised it in English, we (the first author) have translated it in Romanian and have used it in a previous experiment on a large (N=240) Romanian sample of both young and old participants.

The experiment employed a mixed design. Participants were randomly allocated to either a condition without retrieval practice or one with retrieval practice. Participants in the condition without retrieval practice were only tested at two delays: post encoding filled delay and one month. Participants in the condition with retrieval practice were tested at four delays: post encoding filled delay, one day, one week and one month.

During the encoding phase, all participants were presented with four fables read out by the experimenter at a slow and clear pace (2s pause between each sentence and 5s pause between each fable). To minimise any recency effects, each presentation phase was followed by a written one minute filler task, involving finding as many words as possible from the letters composing the Romanian word “hippopotam” (see Baddeley et al., 2019). Participants then took the initial post encoding filled delay cued recall test on one subset of questions (there were four subsets in total), which was self-paced. If participants scored less than 70% correct (9 out of 13 questions), the four fables were presented again (in a different order);
participants took the one minute filler task again and were then retested. Our aim was to repeat this process until participants reached the 70% criterion or to a maximum of four trials. The subsets were randomised both during the encoding phase (in the cases where more trials were needed) and across the various testing delays. In condition without retrieval practice (former single test) one of the subsets not tested at 1-min was randomly selected. In the condition with retrieval practice testing material changed at each delay. The encoding phase and initial test were conducted face to face while all other tests were conducted by telephone. This type of testing, telephone follow-up, has been validated by Baddeley et al. (2013) and used successfully in other studies with similar procedures (Baddeley et al., 2019) as well as studies involving different clinical samples (Walsh et al., 2014).

2. 3. Material
The material comprised a simplified version of the Fables test previously devised for another study investigating the effects of partial repeated testing on forgetting in younger and older healthy individuals. After piloting with a small AD group, the Fables test was modified to make it more accessible for clinical use (Supplementary material for details). The material used in this experiment consisted of four fables loosely mimicking Aesop’s style. Each was four sentences-long and involved eight main features (e.g., characters, nationality, moral of the fable, etc.; full material in the Supplementary material). This generated 52 questions, which were split across four subsets. Each question in the subsets probed one sentence from each of the four fables, without ever probing the same feature twice (in the same story) within the same subset. All materials were presented in Romanian. The original Aesop’s stories are not part of the Romanian culture, not only did we select unrenowned fables, but we also enquired (some participants) at the end of the experiment if any of these were even vaguely familiar to them to ensure they were not.

3. Data availability
The data that support the findings of this study are available from the corresponding author, upon reasonable request.

4. Results
4. 1. Initial learning
There was a significant difference between the two groups in the number of trials necessary to reach the criterion performance level set at 70% correct (t = 7.647, P < .001) with AD groups requiring more trials (M= 2.64, SD= .86) than the HC groups (M=1.4, SD.48). Cohen’s effect size value (d = 1.673) suggested that the effect of group on the number of trials required to reach the 70% criterion was highly significant. Among the 42 HC, 27 required one trial and the remaining required two trials to reach criterion. Out of the 40 AD patients, two required one trial, 15 required two trials, 13 three trials and 3 four trials. Seven AD patients who did not reach the 70% criterion were excluded from the analysis. Therefore the final AD sample included in the analysis below consisted of the 33 AD patients who had reached criterion at encoding. Even after excluding the AD patients who did not reach criterion, the number of trials to reach this criterion was still not equal between AD and HC.

Mixed effects models were used to examine how groups (AD vs. HC) and testing condition (without retrieval practice, with retrieval practice) may have affected recall performance at different delays. In order to control for individual variability among participants we used a model assuming random intercepts and random slopes for each participant, and a covariance structure to account for heterogenous variances at different delays in each linear mixed-effect. Further information on individual performance can be found in Figure 1 and in the Supplementary material in the Individual performance data and tables section.
Fig. 1. Individual recall performance on the Fables test in the immediate, one day, one week and one-month tests in the AD and HC groups.

AD: Alzheimer’s disease; HC: Healthy controls.

Random intercepts and an unstructured covariance matrix were used to account for within-subject correlations. A random effect of delay was also included in order to measure the variance in the effects of delay on scores, across participants. The significance of each fixed effect in predicting each behavioural outcome measure was assessed with $\alpha = 0.05$. A total of 248-230 data points were available for statistical analyses. Mean scores at different time intervals for each of the 4 groups are displayed in Table 4.

AD: Alzheimer’s disease; HC: Healthy controls.

4. 2. Accelerated long-term forgetting in AD

The first mixed effects model compared recall performance across two delay intervals only (post encoding filled delay retrieval and one month) between AD and HC samples, separately for each condition. The model included correct scores as the dependent variable and 2 factors: delay with two levels (post encoding filled delay retrieval and one month) and sample (AD and HC). Significant main effects were found in each testing condition for delay (Without retrieval practice condition: F(1, 33) = 491.851, P<.001; With retrieval practice condition: F(1, 38) = 88.360, , P<.001) and sample (Without retrieval practice condition: F(1,
Pairwise Comparisons showed that HC performed significantly better than AD at post-encoding retrieval test (MD=-1.28 SE=.41, P<.001 = .004) and at one month test (MD=2.32
SE=.77, p=.005) in the condition with retrieval practice as well as in the condition without retrieval practice (post-encoding retrieval test (MD=0.62 SE=.26, P<.001 = .023) and at one month test (MD=1.47 SE=.55, p <.001). Thus, HC participants had a significantly better performance on post-encoding retrieval test and at one month test compared to AD, in both conditions, however there is no evidence of a difference between the rate of forgetting over one month delay in AD group compared to the HC in any testing condition (forgetting rates from post-encoding retrieval to one month were essentially parallel between the groups - Fig. 2).

**Fig. 2.** Mean recall performance on the Fables test at post-encoding retrieval and one-month delays as a function of group (AD and HC) in both testing conditions (single testing; repeated testing).

AD: Alzheimer’s disease; HC: Healthy controls.
4. 3. The testing effect
We ran a linear mixed effects model with main effects of delay, condition and sample and their interactions including the three-way interaction between all main effects as predictors. All three main effects, and the interaction between delay and condition, reached significance. The three-way interaction between delay, sample and condition was not significant (F(2, 71.000)=1.140, p=.326).

The second mixed effects model investigated the change in recall performance (mean correct scores) across 2 delay intervals (post-encoding retrieval; one month) between the 2 conditions (condition without retrieval practice vs. condition with retrieval practice). The analysis was performed separately for each group (AD, HC). Where statistically significant differences between conditions in rate of decline (i.e., a significant condition by delay interaction) were identified, model-based estimates for each delay were computed.

Significant main effects were found in each sample for delay (AD: (F(1, 27)=218.408 P<.001); HC: (F(1,40)=185.253 P<.001) and condition (AD :F(1, 17)= 18.621, P<001; HC: F(1,40)=35.926, P<.001). There was also a significant interaction between delay and condition in each group (AD: (F (1, 27) = 10.515 P<.001); HC: F (1,40)=35.926, P<.001). AD participants in the condition with retrieval practice (M= 5.1, SE=.47) performed significantly better at one month (MD=3.105, SE=.721, p<.001) compared to AD participants in the without retrieval practice condition (M=2, SE=.547) while their performance on post-encoding retrieval test was similar (MD=.293, SE=.327, p=.416; (AD -With retrieval practice condition: M= 9.58, SE=.21; AD- Without retrieval practice condition: M= 9.29, SE=.25; MD=.29 SE=.33, p=.416). Three AD participants in the condition without retrieval practice performed at floor at the one month assessment.

HC participants in the with retrieval practice condition (M=7.43, SE=.47) performed significantly better at one month test (MD=.3.95, SE=.66 P<.001, Cohen's d = 1.896) than HC participants in the without retrieval practice condition (M=3.48, SE=.47), there was also a statistically significant difference in post-encoding retrieval mean scores (MD=.95 SE=.40 p=. 023) with higher mean scores in the with retrieval practice condition (M=10.88 SE=.29) compared to HC in the without retrieval practice condition (M=9.91 SE=.29). A one-way ANCOVA was conducted with the scores from the HC group to compare the effect of condition on performance at one month test whilst controlling for scores on post-encoding
retrieval test. Results showed that the significant effect of condition still holds ($F(14,39) = 28.092, P<.001$). Therefore, the HC participants in the with retrieval practice condition performed significantly better at one month test compared to HC participants in the without retrieval practice condition even after controlling for the differences in performance on post-encoding retrieval test (Fig. 3).

4. 4. **Summary of results**

AD patients showed a significant learning deficit (requiring more trials to reach criterion) and significantly impaired recall performance on post-encoding retrieval test, as well as at one month test compared to HC. However, AD patients did not show ALF between post-encoding retrieval and the one month test in any of the testing condition.
In both conditions both groups declined in recall performance at one month test compared to post-encoding retrieval test, but the decline was significantly smaller for the groups in the condition with retrieval practice (See Figure 3). This suggests that repeated-testing reduces forgetting at one month delay, producing gains in long-term retention in both AD and HC, even when retesting does not involve relearning of the tested material as different features of the initially learnt material were probed at each trial.

5. Discussion

Our study had two aims: (1) to investigate whether people with AD show accelerated long-term forgetting (ALF) relative to HC and (2) to investigate whether people with AD benefit from repeated testing.

5.1. Accelerated long-term forgetting in AD

Some authors have argued that AD memory impairment is characterised predominantly by an acquisition deficit (e.g., Kopelman, 1985; Greene et al., 1996; Grober and Kawas, 1997), whereas others have emphasised forgetting (e.g., Moss et al., 1986; Hart et al., 1988).

The AD patients in our study did differ from HC in learning rate and showed impaired performance compared to HC at all testing delays. Patients also needed more trials to reach criterion compared to HC. Loftus (1985) has noted that differences in initial learning ability may confound analyses of forgetting rates. Other authors have also suggested that forgetting rates may be underestimated in a lower-performing group, as they have less material to forget. In the present study, we attempted to avoid this pitfall by training all participants to a preset criterion (70% correct). All participants reached this criterion (after varying encoding trials), apart from seven patients who did not, and were excluded from the statistical analysis. Equating performance between patients and healthy participants can however present with its own limitation. Issac and Mays (1999) mention that matching procedures can in turn bias against findings that amnesiacs forget faster than controls. In order to match groups at encoding, patients invariably need longer or multiple exposures to test material compared to controls. Therefore, because the mean item-presentation-to-test delay is longer for patients, this can lead to an underestimate of the patients' forgetting rate (Issac & Mays, 1999). When two memories are of the same strength, but different ages, the older one will generally
decline slower (see Mayes, 1986, 1988). Our design cannot exclude these possible very early consolidation differences between Alzheimer patients and controls.

The results of our study speak against the occurrence of accelerated forgetting of verbal material in AD patients over the course of one month. When comparing performance from post-encoding retrieval to one month test, AD patients did not show ALF in either the condition with retrieval practice or the condition without retrieval practice.

When investigating ALF a combination of recognition and free recall is recommended (Elliot et al., 2014). We acknowledge the lack of a free recall measure as a limitation of the current experiment. A free recall measure could be easily devised for the current test (as in the case of the Crimes test- Baddeley, 2013). However, free recall would be affected by disturbances of executive functions and attention that typically characterise dementia, in addition to anxiety or depression (Cerciello et al., 2017). It is also likely to reflect the level of motivation. Recognition is less affected by these variables (Cerciello et al., 2017). The present study was influenced by the Crimes Test study (Baddeley, 2013) where unpublished research (Alber, 2014) showed more variability within a normal sample for free than for cued recall, presumably because cuing reduces the influence of strategy and criterion effects.

5. 2. The testing effect
We compared the performance of the 33 people with AD with that of the 42 age and education matched HC on the Fables cued recall task. By splitting both samples into two groups based on the testing condition (condition with retrieval practice vs the condition without retrieval practice) we were able to disentangle the effect of repeated testing from that of forgetting, thus accurately measuring the impact of repetition on final performance. Three of the AD patients had reached floor, at one month, in the condition without retrieval practice. However, ceiling and floor effects are considered to be a problem if more than 15–20 % of respondents achieved either the best or worst possible score (Garin, 2014). The 3 AD patients do not represent more than 15-20% of our sample. Both AD patients and HC in the condition without retrieval practice showed significantly faster forgetting at one month delay compared to the condition with retrieval practice. Therefore, the condition with retrieval practice benefited both HC and AD participants.

We should however acknowledge that repeated testing is not the only factor which can affect differences in forgetting rates. Several studies have found differences based to type of
assessment, e.g. free recall versus recognition (Green & Kopelman, 2002; Kopelman & Stanhope, 1997; Isaac & Mayes, 1999a), type of material, e.g. verbal versus visuo-spatial material (Lucchelli & Spinnler, 1998; Manes et al., 2005; Davidson et al., 2007) and possibly test difficulty (Freed & Corkin, 1988). Isaac and Mayes (1999a) found accelerated rates of forgetting for semantically related word lists and normal rates for free recall of lists of unrelated words in amnesics. However, recognition and cued recall of both kinds of word lists appeared to decline at a normal rate. They interpret these differences in forgetting patterns as arising from impairments in long-term memory consolidation for complex associations (between 2 or more items). While our material does examine complex associations (between several features), our results may only apply to material that is integrated (such as narrative) where probing one aspect of an integrated narrative might activate the entire narrative. While in the case of material with lower integration, this might not be the case. Probing subparts of material that is not integrated (such as individual words or images), may fail to prime recall of the other subparts.

Additionally, while the use of truly independent items and test forms would probably produce no benefits in performance with repeated testing, they also raise several issues. These would require more intensive initial learning time and would be more challenging to use with patients (Baddeley et al., 2019). Several approaches to repeated testing have been adopted in previous studies. Cassel, Morris, Koutroumanidis, and Kopelman (2016) studied memory for verbal and visuo-spatial material over delays between 30 s and a week in temporal lobe epilepsy patients. They initially required participants to learn four separate stories and four routes, then tested retention of one story and one route per delay. Their method has the advantage of testing each item once. However the drawback is a relatively heavy initial learning load, though the encoding criterion was of only six out of a possible ten correct answers. This procedure can limit potential sensitivity to scores between zero and six at each testing occasion, in some participants. A further problem is that of serial order effects during initial learning potentially favouring primacy, recency or both, which may be further complicated by test order and possible between-test interference effects (Baddeley et al., 2019). Similarly, Jansari, Davis, McGibbon, Firminger, and Kapur (2010) tested a single patient with temporal lobe epilepsy using ten stories, testing two at each of five delays, one by recall and one by recognition. Evidence of ALF was observed that was not found when the same story was tested repeatedly. McGibbon, Firminger, and Kapur (2010) study provides important information, however requiring participants to learn ten stories would make this
test impracticable with a clinical population.

Nonetheless, the fact that both AD and HC benefit from repeated testing to the same extent can have major practical implications. Repeated testing can thus be employed to avoid floor effects (a frequent methodological confound) in studies comparing forgetting rates between AD and HC, without compromising the validity of the comparison.

6. Conclusion

To the best of our knowledge, this study presents the first assessment of long-term forgetting in AD patients over an interval of one month. It is also the first study to compare forgetting rates in AD under a condition with retrieval practice to a one without retrieval practice. By doing so we were able to uncover the importance of the number of tests and the length of test intervals when comparing forgetting rates in clinical and healthy groups over longer periods of time than have been common in previous studies.

Compared to the majority of studies on practice effects, which use within subjects’ design, we employed a between subjects’ design that allowed us to separate the effects of retesting from the effects of delay. Therefore, we are able to quantify more accurately the magnitude of this effect and show that performance is improved under repeated testing conditions, even with partial testing (sampling different features from each fable on every test session/delay).

Our results have potential practical implications in designing strategies/interventions for AD, as well as informing methodological design in clinical trials. Firstly, interventions that can be demonstrated to be efficient in aiding patients to remember important information over prolonged periods of time, are increasingly needed. Both patients and carers seek practical advice from professionals on neuropsychological interventions that will engage remaining capabilities of AD patients and are proved to promote and prolong independent functioning (Camp, 2001; Clare et al., 2002; Clare and Woods, 2004). Our results offer supporting evidence that repeated testing can be used to improve AD patients long-term memory performance. Secondly, repeated testing is used in clinical assessment as well as in clinical trials and research, the evidence that repeated testing (even when only subparts of material are being tested) increases performance for both healthy and clinical patients’ needs to be
carefully taken into account when employing this type of design. Practice effects have been shown to result in type 1 or type 2 errors (Goldberg et al., 2015). Goldberg et al. (2015) have drawn attention to the fact that ignoring practice-effect-related gains in performance produce large sources of errors and increase the likelihood of misinterpretation of the outcomes of clinical trials.

In conclusion, our study adds to the previous literature showing that memory impairment in AD disease is primarily characterised as an encoding, or storage deficits, rather than as accelerated forgetting. Our study also shows that re-testing at multiple delay increases long-term memory performance compared to a single test. The beneficial effect of re-testing holds also in people with AD.
