Abstract
Soluble fibres (non-starch polysaccharides, NSP) from edible plants but particularly plantain banana (Musa spp.), have been shown in vitro and ex vivo to prevent various enteric pathogens from adhering to, or translocating across, the human intestinal epithelium, a property that we have termed contrabiotic. Here we report that dietary plantain fibre prevents invasion of the chicken intestinal mucosa by Salmonella. In vivo experiments were performed with chicks fed from hatch on a pellet diet containing soluble plantain NSP (0 to 200 mg/d) and orally infected with S. Typhimurium 4/74 at 8 d of age. Birds were sacrificed 3, 6 and 10 d post-infection. Bacteria were enumerated from liver, spleen and caecal contents. In vitro studies were performed using chicken caecal crypts and porcine intestinal epithelial cells infected with Salmonella enterica serovars following pre-treatment separately with soluble plantain NSP and acidic or neutral polysaccharide fractions of plantain NSP, each compared with saline vehicle. Bacterial adherence and invasion were assessed by gentamicin protection assay. In vivo dietary supplementation with plantain NSP 50 mg/d reduced invasion by S. Typhimurium, as reflected by viable bacterial counts from splenic tissue, by 98.3% (95% CI, 98.1–99.7; P<0.0001). In vitro studies confirmed that plantain NSP (5–10 mg/ml) inhibited adhesion of S. Typhimurium 4/74 to a porcine epithelial cell-line (73% mean inhibition (95% CI, 64–81); P<0.001) and to primary chick caecal crypts (82% mean inhibition (95% CI, 75–90); P<0.001). Adherence inhibition was shown to be mediated via an effect on the epithelial cells and Ussing chamber experiments with ex vivo human ileal mucosa showed that this effect was associated with increased short circuit current but no change in electrical resistance. The inhibitory activity of plantain NSP lay mainly within the acidic/pectic (homogalacturonan-rich) component. Supplementation of chicken feed with plantain NSP was well tolerated and shows promise as a simple approach for reducing invasive salmonellosis.

Introduction
Salmonella enterica infection in humans is associated with self-limiting diarrhoea, fever, and abdominal pains [1,2]. In England and Wales, 9,685 human cases of Salmonella infection were confirmed in 2010, the most commonly isolated serovars Salmonella enterica Enteritidis and Salmonella enterica Typhimurium [3]. Poultry-related products are one of the major sources of Salmonella infection for humans [2,4,5]. Salmonella also causes considerable worldwide economic loss through chicken mortality, primarily caused by the avian-adapted serovars S. Gallinarum and S. Pullorum [6,7]. Pigs are also a frequent source of zoonotic infection [8]. The prevalence of Salmonella in pigs varies from 7.9 to 30% depending upon the country [8–10].
Vaccination has been successfully used to reduce Salmonella in laying hens, however the cost and practicalities make vaccines unsuitable for use in broilers. The use of therapeutically antimicrobials against Salmonella is increasingly limited in poultry production due to problems with the emergence of resistant epidemic isolates [1].

Since there are no vaccines to prevent salmonellosis, or indeed other food-borne bacteria in humans, there is a clear need for an alternative preventative approach.

Various substances have been investigated for their potentially inhibitory effects on Salmonella infection and faecal shedding, including butyrate [12], honey [13], acidification of feed using lactic, formic and acetic acid [14,15], glutamine [16], glycopeptides derived from soybeans [17], and partially digested whey protein [18]. Butyrate showed promising results for reducing Salmonella colonisation in chickens in vivo via up-regulation of host defence peptides [12]. Acidified feed also inhibited Salmonella shedding in pigs, [15], but other interventions showed limitations, such as possible cytotoxicity to cell monolayers at high concentrations [18], or attenuated effects in vivo [14,16].

We have previously demonstrated that soluble NSP from plantain banana (Musa spp.), inhibits the adhesion of Escherichia coli to, and invasion into, human intestinal epithelial cells [19] and translocation across specialised microfold (M)-cells of the follicle-associated epithelium (FAE) cultured in vitro [19,20]. Subsequently we recently described that soluble plantain NSP was also able to block adhesion of various enteric gut pathogens to the human intestinal epithelial cell-line Caco2, including S. Typhimurium, Shigella sonnei, Clostridium difficile and diarrhoeagenic enterotoxigenic E. coli (ETEC) [21], with the only exception being enteropathogenic E. coli, where plantain NSP did not block bacterial adherence [21]. In the same study, soluble plantain NSP was also shown to block translocation of S. Typhimurium across M-cells in culture and ex vivo human ileal FAE mounted in Ussing chambers [21]. Other soluble plant NSP preparations, such as broccoli NSP, have also showed significant ability to block pathogen-epithelium interaction [20].

We therefore speculated that soluble plantain NSP may also inhibit Salmonella in an un-manipulated animal model. To investigate this we performed additional in vitro experiments to assess the inhibitory action of plantain NSP on Salmonella interaction with porcine-derived intestinal epithelial cells (BJ01X cell-line) and primary chicken caecal crypts. We also conducted an in vivo study to investigate the protective potential of dietary supplementation with soluble plantain NSP in a model of invasive salmonellosis in inbred White Leghorn Line 0 chicks.

**Results**

Supplementation of chick feed with soluble plantain NSP reduces *S. Typhimurium* 4/74 translocation to the spleen in vivo

In chicks ingesting a custom-made commercial pellet diet supplemented with soluble plantain NSP there was a significant reduction observed in the translocation of *S. Typhimurium* 4/74 across the chick gut. The most profound effect observed, with all three doses of ingested soluble plantain NSP (12.5, 50 and 200 mg/d; all *P*<0.05 Kruskal-Wallis), was a significant reduction in Salmonella found in the splenic tissue (e.g. CFUs reduced in splenic tissue by 98.9% [95% CI, 98.1–99.7] 3 d post-infection, in birds on 50 mg/d plantain NSP (N = 5 birds, n = 2 replicates) compared to those birds on a non-supplemented NSP control diet (N = 5, n = 2; *P*<0.0001); **Figure 1A**. Supplementation with soluble plantain NSP had little effect on presence of *S. Typhimurium* CFU cultured from the liver, excepting at 10 d post-infection (*P*<0.05), however bacterial counts in the liver were orders of magnitude lower than spleen counts. There was no significant effect of plantain NSP supplementation on the total CFU observed within the caecal lumen at all doses of plantain NSP supplementation, with the exception of some reduction at day ten with one dose only, compared to birds fed a control diet (see **Figure 1B** and **1C**).

Consistent with *S. Typhimurium* infection in birds of this age, mild inflammation of caecal tissue was seen in all infected birds receiving the standard commercial pellet feed (i.e. not receiving plantain NSP). Livers from infected birds exhibited mild perportal

![Figure 1. Dietary supplementation with soluble plantain NSP reduces *chick salmonellosis in vivo*. (A) Following infection of 8 day-old inbred specified pathogen-free White Leghorn Line 0 chicks with *S. Typhimurium* 4/74, soluble plantain NSP supplementation of a commercial pellet feed significantly reduced bacterial numbers found in the spleen 3 d post-infection. (B) Supplementation with soluble plantain NSP had little significant effect on presence of *S. Typhimurium* CFU cultured from the liver, excepting at 10 d post-infection. (C) Total CFU observed within the caecal lumen were relatively unchanged at all doses of plantain NSP supplementation compared to birds fed a control diet. Significant differences from control (non-supplemented NSP) diet, * P<0.05; ** P<0.01; *** P<0.0001 Kruskal-Wallis (N = 4–7 birds, n = 2 replicates).](https://doi.org/10.1371/journal.pone.0087658.g001)
and multifocal lymphoplasmacytic, histiocytic, and heterophilic infiltrates, with variable single cell hepatocellular necrosis. Focal necrosis was only seen in 5/36 livers examined, two of which were in control feed birds, whilst the other was in the group fed 50 mg/d plantain NSP. No significant abnormalities were observed in spleen and ileal tissue sections taken from all treatment groups.

Further experiments to clarify the mechanism of inhibition of *Salmonella* spp. interaction with intestinal epithelia: in *vitro* studies

Soluble plantain NSP, at 10 mg/mL, reduced adhesion of *S. Typhimurium* 4/74 to primary caecal crypts isolated from 14-day old Lohmann Brown Classic egg-layer chicks (mean reduction of 82% (95% CI, 75–90), N = 4 birds, n = 3 replicates; P<0.001 Mann Whitney U test); Likewise, plantain NSP reduced strain 4/74 adherence to caecal crypts from 33-day old Hubbard JA57 broiler chickens by 42% (95% CI, 19–64), N = 3, n = 2; P = 0.05 (see Figure 2). No significant effects on cryp viability were observed with either soluble plantain NSP pre-treatment nor during the 90 min infection with *S. Typhimurium* 4/74 as assessed by adenylate kinase release into the culture medium (with levels within 90–98% of vehicle-treated control cells).

Plantain NSP at 10 mg/mL also reduced adhesion of *S. Typhimurium* 4/74 (as used in the *in vivo* infection studies) to human Caco2 cells (56% (95% CI, 46–65) reduction in adhesion (N = 3, n = 4) albeit to a lesser extent than that seen for *S. Typhimurium* LT2-infected human Caco2 cells (81% (95% CI, 65–90); both P<0.001 Kruskal-Wallis); see File S1.

Pre-treatment of the porcine B1OXI enterocyte-like cell-line with soluble plantain NSP also significantly inhibited adhesion and invasion of *S. Typhimurium* LT2 in a dose-dependent manner. Similar results were observed for plantain NSP in blockade of *S. Typhimurium* 4/74 to porcine enterocytes (Figure 3). Peak reduction in both adhesion to, and invasion of B1OXI cells, was observed at concentrations of 10 mg/mL soluble plantain NSP; e.g. mean reductions in *S. Typhimurium* adherence compared to vehicle-treated control were 75% (95% CI, 66–84) and 73% (95% CI, 64–81) for strains LT2 and 4/74 respectively (N = 3, n = 4; both P<0.01 Kruskal-Wallis). In addition, soluble plantain NSP also significantly blocked adhesion of *S. Enteritidis*, another key *Salmonella enterica* serovar relevant to production animals, with an 80% reduction (95% CI, 73–87) seen using 10 mg/mL plantain NSP (N = 3, n = 4; P<0.001 Mann Whitney U test), see File S2.

![Figure 2. Soluble plantain NSP reduces adherence of *S. Typhimurium* 4/74 to primary caecal crypts. Soluble plantain NSP (10 mg/mL) reduced adherence of *S. Typhimurium* 4/74 to porcine caecal crypts isolated from both (A) 14-day old Lohmann Brown Classic egg-layer chicks (N = 4 experiments, n = 3 replicates; *** P<0.001 Mann Whitney U) and (B) 33-day old Hubbard JA57 broiler chickens (N = 3, n = 2; * P = 0.05 Mann Whitney U). doi:10.1371/journal.pone.0087658.g002](image)

The effects of soluble plantain NSP on epithelial adherence of *Salmonella* spp. are mediated via an effect on the epithelium that is associated with a marked increase in short-circuit current

In additional experiments using B1OXI cells, we were able to demonstrate that plantain NSP blockade of *Salmonella* adhesion to cell monolayers acts primarily through action on the epithelium. When plantain NSP (5 mg/mL) was added to monolayers 30 min prior to infection, then removed by three washes with sterile PBS (1 min each; at 37°C), levels of adherent *Salmonella* were observed to be significantly reduced (59.2±5.0% inhibition compared to untreated control; N = 1, n = 3; P<0.001 Kruskal-Wallis), albeit lower than that seen in experiments where plantain NSP was added to cells for 30 min without removal before infection (89±5.0% inhibition; N = 1, n = 3; P<0.001); see Figure 4. In contrast, plantain NSP added to bacteria for 30 min, and then removed by centrifugation before re-suspension of bacteria in antibiotic free media and inoculation of B1OXI cell monolayers, resulted in much less inhibition (22.3±10.5%) compared to untreated control (100%; Figure 4).

We have recently shown that plantain NSP (5 mg/mL) blocks translocation of EGP-expressing *S. Typhimurium* LT2 across human ileal follicle-associated epithelium (FAE) mounted in Ussing chambers [21]. We now report that this is associated with a marked increase in transmucosal short circuit current (*Isc*), indicating increased ion efflux. Pre-treatment of tissue with 5 mg/mL plantain NSP for 20 min prior to infection, increased transmucosal *Isc* with the peak change seen at T30 min post-infection (Δ*Isc* 5.86±1.89 μA.cm⁻²), N = 4, with n = 2 replicates; P<0.001 ANOVA vs. untreated control tissue (see Figure 5A). Comitomitant changes in potential difference (PD) across ileal FAE were also observed in response to plantain NSP treatment; P<0.05 ANOVA (Figure 5B). *Salmonella* infection alone resulted in no change in transmucosal *Isc* nor electrical PD in non-plantain ileal FAE (Figure 5A-B). Trans-epithelial electrical resistance (TEER) was maintained throughout the 2 h Ussing chamber experiments of both infected plantain NSP pre-treated ileal FAE and buffer-treated controls, although interestingly there was a trend to a more stable TEER following treatment with soluble plantain fibre (Figure 5C).

The inhibitory effect of plantain NSP on *Salmonella*-intestinal epithelial cell adherence is mediated primarily by the acid (pectic) polysaccharide fraction

At 5 mg/mL, the acidic polysaccharide fraction of plantain NSP isolated by Q-Sepharose eluted from the sepharose with 92% (95% CI, 85–100) and was at least as effective as the unfractionated soluble plantain fibre (86% (95% CI, 85–100), whereas the neutral polysaccharide fraction had lower inhibitory activity (47% inhibition of adhesion (95% CI, 21–72); both P<0.05 compared to vehicle–treated control cells (N = 2 experiments, n = 3 replicates, Kruskal-Wallis; see Figure 6). The acidic fraction was also shown to inhibit adhesion of *S. Typhimurium*.
Typhimurium LT2 to porcine B1OXI enterocytes by 52% (95% CI, 27–76; \( P, 0.05 \)), with the neutral fraction having no inhibitory activity (\( N = 1, n = 4, P, 0.01 \)).

Composition analysis reveals the pectic fraction of plantain NSP to be mainly or only homogalacturonan. The whole plantain NSP preparation as tested in these studies contained substantial maltodextrin (added up to 40% by weight to facilitate resolubilisation after freeze-drying – see Methods) and 2.5% by weight of galacturonic acid, indicating the presence of pectic material (see File S3). Composition of the acidic plantain NSP fraction, obtained by Q-Sepharose anion-exchange fractionation contained approximately 15% (by weight total carbohydrate) of galacturonic acid. On acid hydrolysis and digestion with Driselase®, negligible rhamnose, galactose or arabinose was formed from the acidic fraction nor from the whole plantain NSP, indicating little or no rhamnogalacturonan-I and rhamnogalacturonan-II; File S3. Thus, the pectic material within the acidic fraction of plantain NSP is mainly or only homogalacturonan. The neutral plantain NSP fraction contained no detectable galacturonic acid indicating absence of pectic material.

Discussion

These studies show that supplementation of pelleted feed with soluble plantain NSP was well tolerated by chickens and reduced \( S. \) enterica serovar. Typhimurium 4/74 translocation as shown by reduction in splenic bacteria. Histopathological findings were consistent with \( S. \) Typhimurium infection in birds of this age as

previously described [22]. This is the first time that dietary supplementation with soluble plantain NSP has been shown to block bacterial invasion in an animal model. Soluble plantain NSP also reduced adherence of *S. Typhimurium* to caecal crypt

**Figure 4. Soluble plantain NSP acts on the epithelium to block interaction of *S. Typhimurium* LT2.** Plantain NSP (5 mg/mL) blockade of adhesion of *S. Typhimurium* LT2 to B10X1 cells under different pre-treatment conditions. (A) Standard pre-treatment of cell monolayers with soluble plantain NSP (30 min), followed by infection for 90 min. (B) Pre-treatment of cell monolayers with soluble plantain NSP (30 min), followed by removal from monolayers using three sterile PBS washes prior to infection for 90 min. (C) Pre-treatment of bacteria with plantain NSP for 30 min, followed by centrifugation, re-suspension of bacteria in antibiotic free media and infection for 90 min. Data (mean ± SEM) expressed relative to adherence of vehicle-treated control (100%); n = 3; **P < 0.01, ***P < 0.001, Kruskal-Wallis. doi:10.1371/journal.pone.0087658.g004

**Figure 5. Soluble plantain NSP increases the transmucosal short circuit current of *ex vivo* human ileal follicle-associated epithelium.** Plantain NSP (5 mg/mL) significantly increased (A) transmucosal short circuit current (Isc), with a concomitant decrease in (B) epithelial potential difference (PD, apical-side negative), during pre-treatment of, and blockade of translocation of *S. Typhimurium* across *ex vivo* human ileal follicle-associated epithelium (FAE) mounted in Ussing chambers. (C) Trans-epithelial electrical resistance (TEER) was maintained throughout the experiment. N = 4, with 2 tissue replicates in each case. *P < 0.05, **P < 0.01, ANOVA. For each tissue, Isc and PD responses were calculated and expressed as the increment change (Δ) for each sampling period. Arrows at T0 min indicate addition of EGFP-expressing *S. Typhimurium* LT2 to the mucosal compartment (1 × 10^8 CFU/mL). Overnight culture of Ussing chamber serosal medium following 2 h infection had already demonstrated soluble plantain fibre to block translocation of *Salmonella* across isolated human FAE in this experiment; see reference [21]. doi:10.1371/journal.pone.0087658.g005
epithelium in primary culture from both egg layers and broilers, and blocked adhesion and invasion of S. Typhimurium strains to porcine B10OXI enterocytes.

These results support previous studies from our group showing that soluble plantain NSP blocks adherence of colonic mucosa-associated adherent, invasive E. coli (AIEC) and Salmonella spp. to human intestinal cell-lines in vitro, with no evidence of any cytotoxicity to epithelial cell monolayers, nor any direct bactericidal activity [19–21]. Plantain NSP supplementation had no consistent effect on caecal lumen Salmonella counts. It is intriguing that soluble plantain fibre appears to exert its inhibitory effect on Salmonella translocation via action on the epithelium rather than through any interaction with bacterial carbohydrate-binding proteins (lectins/adhesins). Further studies using Ussing chamber experiments of human terminal ileum showed that soluble plantain NSP treatment of the epithelium increases basal transmucosal short circuit current (Isc), a measure of active (electrogenic) ion movements mediated by cellular transport processes [23]. The observed changes in Isc are likely as a result of increased epithelial chloride (Cl\(^-\)) secretion, which as a physiological effect will cause efflux of ions and water transport, potentially impeding bacterial translocation. Electrogenic Cl\(^-\) secretion, and associated mucosal hydration, is now recognised as a key component of innate epithelial defence, influencing not only bacterial-epithelial interactions but also influencing the composition of the intestinal microbiome [24]. As part of these recent studies, secretagogues enhanced epithelial Cl\(^-\) secretion and water transport was shown to be particularly effective in reducing Salmonella internalisation to, and translocation across T84 colonocytes by over 70% [24]. Also of interest, is that addition of probiotics to broiler diets has shown similar increases in midjejunal and colonic mucosal Isc, attributed to increased sodium glucose transport [25].

Salmonella serovars such as S. Enteritidis and S. Typhimurium are thought to invade human host intestine initially via the microfold (M) cells of the follicle-associated epithelia (FAE) overlying Peyer’s patches located in the distal ileum and colon [26,27], with invasion of other epithelial cells only occurring after subsequent switch to expression of Spi2 (Salmonella pathogenicity island 2) encoding a type III secretory system to allow bacteria to enter intestinal cells basolaterally and/or directly by the apical pole [28]. S. Typhimurium has also been shown to transform epithelial cells of the FAE into M cells to enhance translocation across the intestinal mucosa [29]. M cells act to sample and translocate bacteria and antigens to mucosal lymphocytes, dendritic cells and macrophages located within basolateral pockets of the M cell. S. Typhimurium has also been reported to cross the epithelium via intra-epithelial dendritic cells [30]. FAE in the gastrointestinal tract of chickens also possess M-like cells that share the characteristic morphological and histochemical features of mammalian M cells [31]. The FAE structures in the chicken are much more diffuse than those seen in humans and perhaps not so developed with respect to antigen uptake [31,32]. The large secondary lymphoid organs of the chicken gastrointestinal tract, the caecal tonsils, which are thought to be the primary site of bacterial invasion, also contain M-like cells [31,33]. This is likely the main site of Salmonella infection for chickens [6,34]. Our own previous work has demonstrated that soluble plantain NSP can block translocation of AIEC, Shigella and Salmonella across in vitro modelled M cells, generated by co-culture of human Caco2 intestinal epithelial cells with Raji B lymphocytes [20–21]. We have also shown soluble plantain NSP to block translocation of AIEC and S. Typhimurium across ex vivo human ileal FAE mounted in Ussing chambers [20,21].

The soluble plantain NSP inhibitory activity against bacterial-epithelial interaction is shown by our in vitro studies presented here to be largely due to the acidic polysaccharide or pectin fraction [35]. It was not feasible to generate the large amounts of this fraction needed to allow testing in the in vivo chick model but the relatively good inhibition achieved by the unfractionated plantain NSP implied that this would not be necessary nor indeed economic for large scale use.

Pectins comprise approximately one-third of the dry weight of primary cell walls (the predominant cell walls of the edible plant parts) in non-poalean monocots such as plantain [36], playing key roles in cell-wall structure and function [37,30]. Pectins are complex polysaccharides, in which at least three distinct domains (homogalacturonan and the rhamnogalacturonans RG-I and RG-II) are covalently linked, the RGs containing large proportions of neutral sugars, especially rhamnose, galactose and xylose, in addition to rhamnogalacturonic acid [36]. Some pectic domains also carry methyl and acetyl ester groups [39]. Pectic polysaccharides interlink to each other, e.g. homogalacturonan domains via Ca\(^{2+}\) bridges [37] and RG-II domains via borate bridges [40]; and neutral wall polysaccharides such as xyloglucan can be glycosidically linked to RG-I [41]. Analysis in this study revealed that the acidic (pectic) fraction of plantain NSP possessing significant inhibitory activity against Salmonella adhesion and invasion was composed mainly or only of homogalacturonan, as negligible rhamnose, galactose or arabinose was formed following hydrolysis indicating absence of RG-I and RG-II. RG-II is resistant to Driselase, but would have been hydrolysed to monosaccharides by acid. The neutral plantain NSP fraction, which showed relatively little blockade of Salmonella-host cell interaction, contained no detectable pectic material. Pectins are not appreciably digested in the mammalian upper gut but are almost completely fermented in the large intestine [42]. Pectin from ginseng has been shown to possess anti-adhesive activity against other gut pathogens such as Helicobacter pylori, and some ability to inhibit haemagglutination by bacteria, including that caused by Staphylococcus aureus and Propanobacterium acnes, but not that effected by E. coli and Lactobacillus acidophilus [43].
Thus, soluble plantain NSP reduces adhesion and invasion of _Salmonella_ spp. _in vitro_, in primary cell culture models, and _in vivo_ in the chicken. This suggests that dietary supplementation with soluble plantain NSP has potential to achieve a useful protection against invasive salmonellosis in animals and man. The epithelial adhesion of other human pathogens such as enterotoxigenic _E. coli_, _Shigella sonnei_, and _Clostridium difficile_ is also inhibited by soluble plantain NSP [20,21]. We have recently described this action of dietary soluble NSP in inhibiting bacteria-host epithelium interactions as a ‘contrabiotic’ effect [44]. _In vitro_ studies suggest that the acidic (homogalacturonan-rich) fraction is particularly inhibitory and the Ussing chamber studies of _in vivo_ cultures suggest that its effect is associated with a marked increase in epithelial ion secretion, most likely chloride. Further studies are indicated to assess the generalizability of this protective effect to other host and pathogen interactions _in vivo_.

**Materials and Methods**

**Ethics statement**

All work was conducted in accordance with UK legislation governing experimental animals under project licences PPL 40/3063 and PPL40/3652 and was approved by the University of Liverpool ethical review process prior to the award of the licence. Chicks were reared in the high-biosecurity poultry unit, University of Liverpool, in secure floor pens at a temperature of 30°C until 3 weeks of age, then at 20°C. Birds were allowed _ad libitum_ access to water and vegetable protein-based laboratory poultry pelleted diets under test. All animals were checked a minimum of twice daily to ensure their health and welfare.

Studies described using human tissue specimens from macro-and microscopically normal terminal ileum were obtained from patients who underwent surgery for colon cancer and who had given their informed written consent as previously described [21]. The study was approved by the Regional Human Ethics Committee; Linköping, Sweden.

**Bacterial strains and growth conditions**

_Salmonella enterica_ serovar Typhimurium LT2 and _S._ Typhimurium 4/74 were obtained from Professor Craig Winstanley (Institute of Infection & Global Health, University of Liverpool) and Professor Mark Stevens (Roslin Institute, University of Edinburgh) respectively. _S._ Typhimurium 4/74 was used for _in vivo_ chick studies, due to its high virulence [45]. Serovar _S._ Enteritidis (P125109) was obtained from Professor Paul Barrow (Veterinary Medicine, University of Nottingham). Bacteria were grown from frozen stocks on solid Luria-Bertani (LB) agar at 37°C, for 24 h. Prior to infection of cultured epithelial cells, all strains of _Salmonella_ were washed three times in sterile phosphate-buffered saline (PBS), pH 7.4 and re-suspended to an OD₅₀₀ nm of 1.0 (_S._ Typhimurium LT2 and _S._ Enteritidis) or 1.2 (_S._ Typhimurium 4/74), equating to ~1×10⁹ CFU/mL.

5. _Typhimurium LT2_, transformed with plasmid pEGFP carrying the enhanced green fluorescent protein gene _egfp_, was used in experiments examining bacterial translocation across _ex vivo_ human follicle-associated epithelium (FAE) mounted in Ussing chambers, as previously described [21].

**Soluble plantain fibre (non-starch polysaccharide) preparation**

Non-starch polysaccharide (NSP) preparations from Confoco plantain flour (Trobana Green Plantain flour; Confoco International Ltd; Ripley, UK) were prepared by Provexis Plc (Windsor, UK) at the Teagasc Food Research Centre (Moorepark, Ireland).

In brief, dry plantain flour was homogenised in reverse-osmosis purified water (ratio 1:2), heated to between 90°C and 100°C for 10 min with continuous high-shear mixing to effect starch swelling and gelatinisation. Following cooling to 25°C, the homogenate was treated with fungal α-amylase Fungamyl® (Novozymes; Bagsvaerd, Denmark) for 2 h at pH 6–7. The mixture was then heated to 72°C for 20 min to fully inactive the Fungamyl enzyme. Insoluble NSP was removed by centrifugation and subsequently, low molecular weight components (<300 Da), including starch degradation products, were removed from the soluble NSP by nanofiltration. The concentrated retentate (containing in addition up to 45% by weight plantain-derived maltodextrin carrier as part of the bulk manufacturing process to counter difficulties in freeze-drying/resolubilisation) was spray-dried to a fine dry powder with a particle size distribution of 50–100 μm and a bulk density of 175 g/L (see File S4).

Plantain NSP concentrations tested for the _in vitro_ studies were selected to be within the range of effective luminal concentrations in the human distal colon that would be readily achievable with dietary supplementation [20] (~5 mg/mL, observed to inhibit adhesion of adherent, invasive _E. coli_, _Salmonella_ and _Shigella_ to human intestinal epithelial cell-lines [19–21]. For the _in vivo_ study, given that chickens each have two caeca with a typical volume of about 1 mL each, usually emptied twice per day, a minimum dietary intake of soluble plantain fibre to give a maximum inhibitory effect on bacterial adhesion (achieved with a final concentration of 5 mg/mL [21]) was calculated to be ~20 mg/d. A typical chick feed intake is 20 g/d of which 5% (i.e. 1 g/d) would usually be fibre. Plantain NSP supplementation was therefore evaluated in the range of 0–200 mg/d/chick.

**Preparation of purified acidic and neutral polysaccharide fractions from soluble plantain NSP**

Initial analytical fractionation of soluble plantain NSP (1.6 g dissolved in 50 mL 50 mM Tris-HCl, pH 7.4) using a HiPrep™ Q-Sepharose® FF 16/10 anion-exchange column on an AKTA-prime plus liquid chromatography system (GE Healthcare Life Sciences, Chalfont St Giles, UK) demonstrated that bound acidic polysaccharides (as determined by uronic acid content) could be eluted step-wise in 50 mM Tris-HCl buffer containing 0.1, 0.5 and 1 M NaCl at a flow rate of 5 mL/min (data not shown). Using this information, a bulk preparation of both neutral and acidic fractions of soluble plantain NSP was then conducted using preparative Q-Sepharose® (counter-ion Cl–) Fast Flow anion-exchange medium (GE Healthcare) in a 2.5 litre container [46]. Q-Sepharose (300 mL) was washed extensively with three 1 L volumes of sterile deionised water and then equilibrated twice with 1 L of sterile-filtered 50 mM Tris-HCl buffer, pH 7.4. Plantain NSP (25 g) was added to 750 mL sterile 50 mM Tris-HCl, pH 7.4, mixed thoroughly for 1 h at room temperature and left to settle overnight at 4°C. The majority upper, clear layer (~700 mL) was removed, filtered under vacuum through a sintered glass funnel and Whatman No.1 filter paper, and then added to a 2.5 L mixing vessel containing Q-Sepharose® and rotated for 1 h, at 4°C. Unbound neutral polysaccharide was collected and filtered again. Following two 15 min washes with equilibration buffer to remove any residual unbound material, Q-Sepharose®-bound acidic polysaccharides were eluted with 800 mL 1 M NaCl in 50 mM Tris-HCl, with rotating overnight at 4°C.

Neutral and acidic polysaccharide fractions were then desalted using multiple pre-packed PD MidiTrap G-10 gravity mini-columns (1 mL per column), eluted with sterile deionised water as per the manufacturer’s instructions (GE Healthcare). Elution
profiles for the purified neutral and acidic plantain polysaccharides on the G-10 mini-columns were established [File S5]. Fractions were assayed for total carbohydrate content, and the void fraction (approximate M > 700) was collected. All columns were calibrated using phenol red (354 Da) as a low molecular size marker. Desalted fractions were shell-frozen in round-bottomed glass vacuum flasks by immersion and rapid rotation in 100% ethanol containing dry ice. Flasks were stored for at least 20 min at −80°C before lyophilisation overnight under vacuum. The total yield of acidic material from 25 g plantain NSP was 1.16 g (4.64% by weight); the total yield of neutral material was 4.21 g (16.84% by weight).

**Assessment of total carbohydrate and uronic acid content of chromatography fractions**

Total carbohydrate content of NSP fractions was assayed using a modified method of Dubois et al. [47]. Briefly, 10 μL fractions were added to 96-well microtitre plates (Corning/Costar) in triplicate, and 100 μL of 4% (wt/vol) phenol dissolved in deionised water was added at room temperature for 5 min. Concentrated sulphuric acid (150 μL) was then rapidly delivered to all wells (with great care) and vigorously aspirated to generate heat required for reaction colour development. Plates were left to cool for 20 min and then measured for A_{540}. Carbohydrate content of samples was determined using a calibration curve of d-glucose (0–20 μg/mL). Hexuronic acid content (α-glucuronic acid and α-galacturonic acid) was measured using a commercial K-URONIC assay (Megazyme International; Bray, Ireland). Plates were run under standard conditions at 200 m for 10 min, as per manufacturer’s instructions.

**Analysis of the hydrolysis products of plantain NSP, and the neutral and acidic NSP anion-exchange fractions**

Plantain NSP and Q-Sepharose derived neutral and acidic NSP fractions were each hydrolysed with either 0.5% Driselase® (a commercial enzyme mixture of hydrolitic enzymes capable of digesting homogalacturonan and rhamnogalacturonan-I (RG-I) efficiently to galacturonic acid and associated neutral monosaccharides) or 2 M trifluoroacetic acid (TFA) as per [48]. Thin-layer chromatography (TLC) was performed on Merck silica-gel plates and on plates pre-washed for in acidified acetone to enhance mobility of the uronic acids. Each loading was derived from 25 μg of plantain NSP or polysaccharide fraction (or contained an equivalent amount of Driselase® or TFA). Plates were run under two solvent conditions, ethyl acetate/pyridine/acidic acid/water (6:3:1:1) and butan-1-ol/acidic acid/water (2:1:1), each followed by staining using thymol/H2SO4. To better determine galacturonic acid yields, high-voltage paper electrophoresis (HVPE) of plantain fibre samples and their hydrolysis products was also performed as per [49]. Briefly, each loading was derived from 200 μg of the fibre or fraction (or contained an equivalent amount of Driselase® or TFA). Electrophoresis was performed using Whatman No. 1 paper in pH 2.0 buffer at 4.7 kV for 80 min, with monosaccharide and oligogalacturonide markers included for reference. Staining was with aniline hydrogen-phthalate [49].

**Salmonella adhesion and invasion assays in mammalian and avian epithelial cells**

The enterocyte-like B10XI cell-line (BioNutriTech; Montpellier, France) originally thought to be from dissected colonic tissue of 19-day old chicken embryos [50], but recently verified as porcine in origin [51] was seeded at 1×10^6 cells/well in 24-well tissue culture plates (Costar; High Wycombe, UK) and maintained in advanced Dulbecco’s-modified Eagle’s medium (DMEM), supplemented with 5% (vol/vol) fetal calf serum (FCS) (Invitrogen; Paisley, Scotland). Media was supplemented with 100 U/mL penicillin, 100 μg/mL streptomycin and 8 μM glutamine (Sigma-Aldrich; Poole, UK). Cultures were maintained at 37°C in a humidified atmosphere of 5% (vol/vol) CO2, 95% air for 24 h.

Prior to infection with *Salmonella* strains, confluent cells were washed three times with sterile PBS and cultured overnight in DMEM without antibiotics. Following 30 min pre-treatment of cells with or without soluble plantain NSP (0 to 10 mg/mL in antibiotic-free DMEM), cells were infected at a multiplicity of infection (MOI) of 20, for 90 min. Each monolayer was then washed with sterile PBS to remove non-adherent bacteria and adherence to, and invasion of, epithelial cells assessed by gentamicin protection assay, as per [19,21]. Cells were lysed with sterile 1% (vol/vol) Triton X-100, serial dilutions performed and bacteria enumerated in triplicate, following overnight growth on LB agar.

Additional experiments were also performed to determine whether action of plantain NSP to block *Salmonella* adhesion was via an action on the epithelial monolayer or direct interaction with bacteria. To test the former, plantain NSP was added to B10XI cells 30 min prior to infection as described above, but then removed by three washes with sterile PBS (1 min each; at 37°C). Monolayers were then provided fresh antibiotic-free DMEM, infected and levels of adherent *Salmonella* assessed. To test for direct interaction with bacteria, plantain NSP was pre-incubated with *Salmonella* for 30 min, followed by centrifugation, resuspension of bacteria in anti-biotic free media and inoculation of epithelial cell monolayers.

Plantain NSP blockade of *S. Typhimurium* 4/74 was also examined *in vitro* using the human colorectal adenocarcinoma cell-line Caco2, as this isolate was to used in the *in vivo* studies, and to compare to our previous studies using *S. Typhimurium* LT2 [21].

As per previous studies [20,21], epithelial cell viability during plantain NSP treatment and infection was carefully monitored by measurement of adenylate kinase released to the culture medium using a ToxiLight™ bioassay kit (Lonza; Walkersville, USA), and confirmed in selected experiments by Giemsa microscopy.

**Primary chick caecal crypt culture and *Salmonella* infection**

Cysts were isolated from the caeca of 14-day old Lohmann Brown Classic egg-layer chickens and, in separate experiments, from the caeca of 33-day old Hubbard JA57 broiler chickens using methods adapted from Van Deun et al [52]. In brief, caeca were transported on ice and washed in Hank’s balanced salt solution (HBSS) supplemented with 20 mM HEPES, 100 U/mL penicillin, 100 μg/mL streptomycin, 50 μg/mL gentamicin and 2 mM L-glutamine. Tissue was cut into smaller pieces and digested in sterile 1% (vol/vol) Triton X-100, serial dilutions performed and bacteria enumerated in triplicate, following overnight growth on LB agar.
supplements were from Sigma. Crypts were incubated at 37°C in 5% CO₂, 95% air, and washed daily with sterile PBS, and media was replaced with supplemented media but with reduced FCS and chicken serum (both 0.5% vol/vol). Crypt viability was determined by measurement of adenylyl kinase released to the culture medium using a ToxiLight™ bioassay kit (Lonza).

Infection assays were all performed 4 d following initial isolation of caecal crypts (seeded at ~7 × 10⁵ crypts per well), with crypts (absent of any contaminating fibroblasts) pre-treated for 30 min either with soluble plantain NSP (10 mg/mL, in DMEM without antibiotics) or vehicle. S. Typhimurium 4/74 (4.2 × 10⁴ bacteria) were added to each well, prior to a 90 min incubation. Crypts were lysed with sterile 1% (vol/vol) Triton-X, serial dilutions were added to each well, prior to a 90 min incubation. Crypts were sequentially removed from each bird. Splenic and liver tissue was replaced with supplemented media but with reduced FCS and 5% CO₂, 95% air, and washed daily with sterile PBS to confirm absence of S. Typhimurium.

Avian histopathology
Post-mortem organs (spleen, liver, caeca and ileum) were each fixed in 4% (wt/vol) paraformaldehyde and embedded in paraffin wax. Sections (3–5 μm) were prepared, dewaxed, rehydrated stepwise through ethanol to sterile water and then stained with haematoxylin and eosin. Tissue sections were reviewed by a qualified veterinary pathologist who was blind to the treatment groups.

Statistical analyses
For the in vitro studies, N numbers indicate the total number of independent experiments performed, where each experiment was performed using n replicates for any individual treatment group. For the in vivo studies, N = number of birds in each treatment group, sacrificed on each day post-infection, with duplicates performed for all sample analyses. Independent treatment groups were assessed for normality and equality of variances, before analysis using Mann-Whitney U test, one-way analysis of variance (ANOVA) followed by selected pairwise comparisons (Bonferroni test) or non-parametric Kruskal-Wallis ANOVA followed by all pairwise comparisons (Conover-Iman) as appropriate. Data are presented as mean ± standard error of the mean (SEM). Differences were considered significant when P<0.05.

Supporting Information
File S1 Contains: Figure S1: Soluble plantain NSP inhibits adhesion of S. Typhimurium strains LT2 and 4/74 to the human intestinal Caco2 cell-line in vitro. Pre-treatment (30 min) with soluble plantain NSP dose-dependently blocked (A) adhesion and (B) invasion of S. Typhimurium 4/74 to human Caco2 cells, at similar levels to that observed for S. Typhimurium LT2 (N ≥ 3 experiments, n = 4 replicates; *P<0.05, ** P<0.01, *** P<0.001, Kruskal-Wallis). Data (mean ± SEM) expressed relative to adherence (or invasion) of vehicle-treated control (100%).

File S2 Contains: Figure S2: Soluble plantain NSP blocks adhesion of S. Enteritidis to the porcine enterocyte cell-line B1OXI in vitro. Pre-treatment with soluble plantain NSP at 10 mg/mL blocked (A) adhesion to, and (B) invasion of S. Enteritidis to B1OXI cells (N = 3, n = 4; ***P<0.001 Mann Whitney U). Data (mean ± SEM) expressed relative to adherence (or invasion) of vehicle-treated control (100%).

File S3 Contains: Figure S3A: Thin-layer chromatography (TLC) of whole plantain NSP, preparative Q-Sepharose neutral and acidic polysaccharide fractions and their hydrolysis products. Samples were hydrolysed with either trilluoroacetic acid (TFA) or Driselase. Each loading was derived from 25 μg of plantain NSP or polysaccharide fraction (the acidic fraction subjected to TLC had been reconstituted in physiological saline and contained ~70% by weight salt, and thus its loading was ~7.5 μg carbohydrate; blanks contained an equivalent amount of Driselase or TFA). All samples contained in addition up to 45% plantain-derived maltodextrin carrier (responsible for the glucose content). Samples were loaded on to...
Merck silica-gel plates pre-washed in acidic acetone to enhance the mobility of the ionic uronic acids. The running solvent was ethyl acetate/pyridine/acetric acid/water (6:3:1:1). The stain was thymol/H2SO4.

Figure S3B: High-voltage paper electrophoresis (HVPE) of whole plantain NSP, preparative Q-Sepharose neutral and acidic polysaccharide fractions and their hydrolysis products. Samples were hydrolysed with either trifluoroacetic acid (TFA) or Driselase. Each loading was performed on Whatman No. 1 paper in pH 2.0 buffer at 4.7 kV for 80 min. Staining was with aniline hydrogen-phthalate.
