Running title

Structural variants at BRCA1/2 and HR deficiency in tumours

Statement of significance

We demonstrate that BRCA1/2 loss by structural variation (predominantly large deletion) are novel and unappreciated events, leading to loss of gene expression in ovarian and other cancers. Structural variants contribute to homologous recombination deficiency and their detection could identify more patients suitable for PARP inhibition, a therapy with proven benefit.

Abstract

Purpose:

The abundance and effects of structural variation at BRCA1/2 in tumours are not well understood. In particular, the impact of these events on homologous recombination repair deficiency (HRD) has yet to be demonstrated.
Experimental Design:
Exploiting a large collection of whole genome sequencing data from high grade serous ovarian carcinoma (N=205) together with matched RNA-seq for the majority of tumours (N=150), we have comprehensively characterised mutation and expression at BRCA1/2.

Results:
In addition to the known spectrum of short somatic mutations (SSMs), we discover that multi-megabase structural variants (SVs) are a frequent, unappreciated source of BRCA1/2 disruption in these tumours, and we find a genome wide enrichment for large deletions at the BRCA1/2 loci across the cohort. These SVs independently affect a substantial proportion of patients (16%) in addition to those affected by SSMs (24%), conferring homologous recombination repair deficiency (HRD) and impacting patient survival. We also detail compound deficiencies involving SSMs and SVs at both loci, demonstrating that the strongest risk of HRD emerges from combined SVs at both BRCA1 and BRCA2 in the absence of SSMs. Further, these SVs are abundant and disruptive in other cancer types.

Conclusions:
These results extend our understanding of the mutational landscape underlying HRD, increase the number of patients predicted to benefit from therapies exploiting HRD, and suggest there is currently untapped potential in SV detection for patient stratification.
Introduction

Homologous recombination deficiency (HRD) is identifiable in many cancers and is particularly prominent in high grade serous ovarian cancer (HGSOC)\(^1\), affecting around 50% of tumours\(^2\) and leaving detectable mutational spectra across the tumour genome\(^3\). The mutational landscape of HGSOC is dominated by extensive genomic copy number changes and structural rearrangement driven by chromosome instability and defective DNA repair, rather than the patterns of recurrent point mutation in tumour suppressor and oncogenes often observed in other solid tumours\(^4,5\).

Germline short mutations (GSM) disrupting the coding sequence of \(BRCA1\) and \(BRCA2\) are the most common types of HRD-associated defect, occurring in 8% and 6% of HGSOC patients respectively, while disruptive somatic short mutations (SSM) in these genes are present in an additional 4% and 3% of HGSOC patients respectively\(^6,7\). These GSMs and SSMs include single nucleotide variants (SNVs) as well as short indels, with frameshifts being the predominant mechanism of inactivation. These \(BRCA\)-deficient tumours represent approximately 20% of patients with HGSOC. An additional 11% of tumours are thought to be \(BRCA\)-deficient through epigenetic silencing of \(BRCA1\)\(^2,8\). Mutational or epigenetic inactivation of other genes involved in the HR pathway are also thought to confer HRD in a smaller proportion of HGSOC patients\(^7,9–12\). Genome-wide patterns of SNVs, indels and structural variation have been identified as strong predictors of \(BRCA1/2\) deficiency\(^3,13\). These mutational signatures of \(BRCA1/2\) deficiency are also found in additional tumours that lack short variants at \(BRCA1/2\), suggesting that other unknown aberrations may also be involved in HRD\(^3\). The demonstration of \(BRCA1/2\) loss and detection of HRD is crucial in the
management of HGSOC\textsuperscript{14–19}, breast\textsuperscript{20,21}, pancreatic\textsuperscript{22} and prostate\textsuperscript{23} cancer to identify patients whose outcome is markedly improved by the administration of PARP inhibitors\textsuperscript{14–16}. PARP inhibitors selectively kill HRD cells since these cells are deficient in HRR (homologous recombination repair) and can neither resolve stalled replication forks nor accurately repair the increased number of double strand breaks that result from the use of these agents\textsuperscript{24}.

The clinical importance of GSMs and SSMs at \textit{BRCA1/2} is well established in cancer\textsuperscript{17,20,25–28}. In contrast, the abundance and effects of structural variants (SVs) at \textit{BRCA1/2} are not well understood, particularly for large SVs (>1Mb) encompassing multi-megabase regions. Similarly, the compound effects of SVs and short mutations occurring simultaneously at \textit{BRCA1} and \textit{BRCA2} are poorly studied. Matched tumour-normal whole genome sequencing (WGS) of freshly-frozen tissue is accepted as the best resource to accurately detect SVs in tumours but in the past such data have been scarce for HGSOC\textsuperscript{29,30}. Here we comprehensively characterise the mutational landscape of \textit{BRCA1/2} in HGSOC using the largest collection to date of uniformly processed WGS data (N=205), comprising two previously published cohorts\textsuperscript{5,6}, as well as a large novel cohort described here for the first time. We document the prevalence of HRD across these three cohorts to reveal the complexity of the mutations associated with HRD, their impact on gene expression and associations with clinical outcome.

\textbf{Materials and methods}

WGS data from matched tumour and normal blood samples were uniformly remapped and analysed to generate a range of somatic mutation calls (Supplementary Figure 1) for three HGSOC cohorts: chemoresistant or relapsed tumours from the Australian Ovarian Cancer
Study\textsuperscript{5} (AOCS) (N=80), pre-treatment WGS primary tumours from The Cancer Genome Atlas (TCGA)\textsuperscript{6} (N=44) and the previously unpublished primary tumours from Scottish High Grade Serous Ovarian Cancer (SHGSOC) study (N=81) of which 16 (20%) have had neoadjuvant chemotherapy. The combined cohort (N=205) presented here was uniformly analysed as follows.

**Scottish sample collection and preparation for WGS**

Scottish HGSOC samples were collected via local Bioresource facilities at Edinburgh, Glasgow, Dundee and Aberdeen and stored in liquid Nitrogen until required. HGSOC patients were determined from pathology records and were included in the study where there was matched tumour and whole blood samples. Tumour samples were divided into two for DNA and RNA extraction and slivers of tissue were taken, fixed in formalin and embedded in paraffin wax (FFPE). Samples were only included if they were confirmed as HGSOC and there was greater than 40% tumour cellularity throughout the tumour, determined using H&E staining of the FFPE sections and pathology review. Somatic DNA was extracted from the tumour and germline DNA was extracted from whole blood. Quality control was then carried out on the resultant DNA to ensure sufficient purity and quality (Supplementary Methods). Only when all quality control requirements were satisfied was the DNA sequenced at the Glasgow Precision Oncology Laboratories.

This study was carried out in accordance with the principles of the Declaration of Helsinki. Ethical approval for the use of human tissue specimens for research was obtained from the Lothian NHS Research Scotland Human Annotated Bioresource (ethics committee reference 15/ES/0094-SR494). Correlation of molecular data to clinical outcome and
clinicopathological variables in ovarian cancer was approved by South East Scotland Research Ethics Committee 2 (reference 2007/W/ON/29). All relevant ethical regulations were complied with, including the need for written informed consent where required.

**Sequence acquisition and availability**

WGS and RNA-seq reads were downloaded in compressed FASTQ format from the sequencing facility (SHGSOC) or in aligned BAM format (including unaligned reads) from the European Genome/Phenome Archive (AOCS) and the Bionimbus Protected Data Cloud (TCGA_US_OV). The reads obtained in BAM format were query-sorted and converted to FASTQ. All whole genome sequence and RNAseq data for the SHGSOC cohort will be made available on publication via EGA.

**Primary processing of WGS**

Reads were aligned to the GRCh38 reference genome and somatic and germline variant calling was run using a bcbio\textsuperscript{44} 1.0.7 pipeline (see Supplementary Information for full pipeline configuration, program, resource versions and references). Germline SNPs and indels were called with GATK 4.0.0.0 HaplotypeCaller. Somatic SNVs and indels were called as a majority vote between Mutect2, Strelka2 and VarDict. Small variants were annotated with Ensembl Variant Effect Predictor v91 and filtered for oxidation artefacts by GATK 4.0.0.0 FilterByOrientationBias. Somatic structural variants were called with Manta 1.2.1 and somatic copy number variants with CNVkit 0.9.2a0. Loss of heterozygosity and somatic copy number variants were also identified with CLImAT. Sample quality control was performed with Qsignature 0.1 to identify sample mix-ups and VerifyBamId 1.1.3 to identify sample contamination. Tumour cellularity was estimated using both CLImAT’s estimates and
p53 variant allele frequency. These measures were compared to the qPure estimates for the AOCS cohort\(^5\) and histopathological estimates for the SHGSOC cohort with very good concordance (Supplementary Figure 2). The CLiMAT estimates were used as the final estimates of cellularity.

**Filtering of small variants (SNVs and indels) at BRCA1/2**

Germline short variants at *BRCA1/2* were filtered to include only damaging pathogenic variants for the purposes of establishing *BRCA1/2* mutational status. Included variants were all of moderate or high impact according to VEP. Variants with a pathogenic or risk factor annotation according to ClinVar\(^45\) were included (n=145). Remaining variants with a ClinVar benign or likely benign status were excluded (n=1147). Remaining frameshift or nonsense (stop gained) or splice donor/acceptor variants were included (n=125). Remaining missense variants with damaging SIFT and PolyPhen predictions were included (n=36). Remaining missense variants called as damaging by only one of SIFT and PolyPhen were considered borderline and were excluded if their CADD score < 20\(^46\). Missense or inframe variants with no Clinvar, SIFT or PolyPhen evidence were excluded.

Somatic short variants at *BRCA1/2* were also filtered for pathogenicity to include variants that: were annotated by VEP as being of high or moderate impact, were pathogenic according to at least one of SIFT or PolyPhen and had a high CADD score. In addition, we excluded somatic variants with an allele frequency less than 0.4.
**Curating a high-confidence list of structural variants at BRCA1/2**

We identified structural variants in HGSOC patients using Illumina’s paired and split read based structural variant detection tool, Manta\(^47\). However, we observed that Manta was failing to detect a large number of very large deletions (>1Mb) that had been identified using depth of coverage-based approaches in PCAWG\(^48\). Therefore, we chose to supplement these calls with copy number variants greater than 1 Mb in size that were called by one caller (CNVkit) using evidence from read depth and were also confirmed by an allele-specific copy number caller (CLImAT) which provides an additional layer of evidence in addition to read depth as it also incorporates the shift in allele frequency of heterozygous SNPs within the potential copy number variant into its variant calling algorithm which also accounts for aneuploidy and sample cellularity. Deletions were assumed to be heterozygous if the copy number as estimated by both CNVkit and CLImAT was 1 although this may be a conservative estimate of allelic loss in the presence of subclones. We visually inspected all the identified structural variants in the Integrative Genomics Viewer (IGV) (v2.4.10). The magnitude of coverage and log fold change were inspected to confirm either duplication or deletion. For structural variants in the range 300bp-30kb, the paired end sequencing reads were manually reviewed including looking at split reads, paired end insert size, read coverage and pair-orientation. We compared our filtered set of large CNVs in the samples included in PCAWG to PCAWG’s copy number calls and found that 40/41 of our variants in these samples were also identified by PCAWG.

**Enrichment of structural variation at BRCA1/2**
Permutation analyses were carried out using the R package RegioneR\textsuperscript{49} to investigate whether large deletions overlap more often with \textit{BRCA1} and \textit{BRCA2} than they do elsewhere in the genome. We carried out 100,000 permutations to simulate the null hypothesis throughout the genome for each gene and judged significance at alpha = 0.05. (Supplementary Figure 3).

We investigated whether large deletions, large duplications and inversions are enriched at \textit{BRCA1} and \textit{BRCA2} within their respective chromosomes using 100,000 circularised permutations to generate the null distribution of overlaps in each case (Supplementary Figure 4). The observed number of overlaps with \textit{BRCA1/2} was well within the range of this null distribution and therefore showed no evidence of within chromosome enrichment which is perhaps unsurprising given the large sizes of these events relative to the length of their chromosomes.

\textbf{Implementation of HRDetect}

To predict the level of HR deficiency in each tumour sample we implemented the HRDetect algorithm as published by Davies and Glodzik et al\textsuperscript{3}. We based our implementation on a Snakemake pipeline made publicly available by Zhao et al\textsuperscript{50}, with some modifications to ensure accurate recapitulation of the original method (Supplementary Methods). As some of the AOCS cohort included here were also used in the validation of HRDetect in the original publication we were able to compare our implementation for the same patients with that of the authors. Our implementation of HRDetect was very highly correlated with the original HRDetect implementation on the same samples (Spearman’s rho = 0.92).
We used the weights for the independent variables that were defined by the original model rather than retraining the model on our data as the original weights trained on a breast cancer dataset have been shown to perform well on ovarian cancer datasets and our total sample size is substantially smaller than that used to train the model originally. As input we used the somatic SNV and indel calls identified by the ensemble calling approach described above; the structural variant calls made by Manta and the copy number segments defined by CNVkit.

**Scottish RNA sample preparation and sequencing**

HGSOC samples were collected and underwent quality control as described for the DNA samples used for WGS. Somatic RNA was extracted from the resulting RNA sample, underwent quality control and was quantified. RNAseq was carried out by the Edinburgh Clinical Research Facility on an Illumina NExtSeq500 (Further details in Supplementary Methods).

**Primary processing of RNA-seq**

RNA-seq data was analysed using the Illumina RNA-seq best practice template. Briefly, reads were aligned to the GRCh38 reference genome and quality control was carried out. Salmon quant\textsuperscript{51} was used to quantify the expression of transcripts against the GRCh38 RefSeq transcript database indexed using the salmon index (k-mers of length 31). Transcript-level abundance estimates were imported into R and summarised for further gene-level analyses. For differential expression analyses, raw expression counts were used by the DESeq2 package\textsuperscript{52}. For visualization of gene expression, counts were normalized using the variance stabilizing transformation. Previously published RNA-seq data available for the
AOCS\textsuperscript{5} (N=80) and TCGA\textsuperscript{6} (N=30) cohorts, together with novel RNA-seq data for the SHGSOC (N=40) cohort, generated for the present study as detailed above, were processed in this way from FASTQ.

**Curation and acquisition of the patient’s clinical information**

*Scottish High Grade Serous Ovarian Cancer (SHGSOC)*

Clinical data for the SHGSOC cohort was retrieved from the Edinburgh Ovarian Cancer Database\textsuperscript{53}, the CRUK Clinical Trials Unit Glasgow and available electronic health records (ethics reference 15/ES/0094-SR751).

*Australian Ovarian Cancer Study (AOCS) & The Cancer Genome Atlas (TCGA)*

The clinical information including survival end-points, age and stage at diagnosis is available for these patients as part of the PCAWG project\textsuperscript{48}.

**Statistical analyses**

All downstream statistical analyses were carried out in R (v3.6.0) using Jupyter notebook (v4.3.1).

**Differential expression analyses of BRCA1/2 in tumours with and without deletions at BRCA1/2**

In order to compare the gene expression levels at BRCA1/2 between tumours with and without BRCA1/2 deletions, we used the package DESeq2 to test for differential expression between the raw gene expression counts at each gene between samples with and without a deletion at that gene. At BRCA1, samples that also had a short variant had significantly
lower expression than those that had a deletion alone. As a result we only considered the samples with a deletion in the absence of a short variant. At *BRCA2*, this was not the case and the samples with short variants in addition to a deletion had comparable levels of expression to those with deletions alone so were included in the analysis. Cohort and tumour sample cellularity were included as covariates in the model formula.

**Univariable analyses of genomic features and risk of HR deficiency**

The risk of HR deficiency in tumours with *BRCA1/2* mutations, grouped by type, relative to those tumours without *BRCA1/2* mutations were determined using Fisher’s exact tests. The effect of mutations at *BRCA1* and *BRCA2* were determined together and, where sample size permitted, separately for mutational categories including: germline short mutations only, somatic short mutations only, single deletion which overlaps at least one exon in the absence of a short variant or other SVs, deletion of at least one exon at both *BRCA1* and *BRCA2* in the absence of a short variant, inversion spanning *BRCA1* in the absence of short variants or deletion and duplication spanning *BRCA2* in the absence of short variants or deletion. We also considered the impact of the presence of a short variant accompanied by a deletion at either of the genes. These categories are further described together with their labels and colour coding in the Supplementary Information. The relative risk conferred by each mutational category was calculated in comparison to the group of patients without *BRCA1/2* mutations or SVs. Samples where *BRCA1/2* promoter methylation had been detected were excluded except for where the effect of *BRCA1* promoter methylation was itself being examined. All samples with *BRCA1* promoter methylation are predicted to be HR deficient so pseudo counts of 1 are used to estimate the effect size which is therefore a likely underestimate. P-values were adjusted for the impact of multiple testing using...
Benjamini-Hochberg correction and were considered together with the effect sizes in the reporting of results.

**Multivariable elastic-net regularised regression model**

Given the relative sparsity of the data and the correlation between features we used a multivariable elastic-net regularised regression model for the binary outcome of HRD defined by a probability of HRD greater than 0.7 from HRDetect. The data were partitioned into train and test sets (80:20) and the tuning parameters were optimised, in order to maximise the AUC, using 10-fold cross validation of the training set. The model was then fitted to the training set and the model performance assessed using the test set. The input variables available for selection were: *BRCA1* germline short variant status; *BRCA1* somatic short variant status; the presence of a large somatic deletion at *BRCA1*; the presence of a large somatic deletion at *BRCA1* and a *BRCA1* short variant; all the corresponding variables for *BRCA2*; the presence of an inversion at *BRCA1*; the presence of a duplication at *BRCA2*; the presence of a large somatic deletion at *BRCA1* and at *BRCA2* (double deletion); *BRCA1* promoter hypermethylation; whole genome doubling; genome-wide load of SNVs, large CNVs and SVs in addition to cohort and tumour cellularity. The data was partitioned and the model optimised and fitted to 100 train-test splits of the data in order to assess the robustness of the feature selection.

**Survival-time analyses of the impact of HRD on overall survival**

Follow up information including overall survival time was available for 190 out of 205 patients, of which 144 were deceased by the time of last follow up. The association between
genome-wide patterns of HRD and progression-free survival was also assessed. Progression-free interval time was available for 151 of the patients from the AOCS and SHGSOC cohorts of which 129 relapsed by the time of last follow up. The effect of the HRDetect score, as a measure of the probability of HRD in the tumour, on the length of time that patients survived after diagnosis (overall survival-time) and the time between diagnosis and first radiologically defined progression (progression-free survival-time) was assessed using Cox proportional hazards models stratified by cohort. Multivariable models were also fitted adjusting for age and stage at diagnosis and the Schoenfeld residuals were examined. In all cases hazard ratios reported correspond to a 1 standard deviation increase in HRDetect score. Survival probability through time was compared between HR deficient (HRDetect score > 0.7) and HR proficient (HRDetect score <=0.7) patients in Kaplan-Meier plots. This was repeated excluding the patients with BRCA1/2 short variants to assess the impact of HRD driven by other events on survival.

**BRCA1/2 SVs in other cancer types and their impact on expression**

We used the consensus SV and CNV calls generated and included in the 2017-01-19 release of PCAWG to investigate the abundance of SVs at BRCA1/2 in other cancer types. Samples (N=2,567) were from all cancer subtypes included in PCAWG that are recommended for use in subtype-specific analyses. Disruptive SVs were identified by intersecting the variant calls with the exons of BRCA1/2. Abundance of SVs, deletions and duplications were tabulated separately for each of the cancer types. Cancer subtypes are ordered from left to right by overall SV burden as determined by PCAWG.
Using gene expression quantifications from matched RNA-seq for N=735 of these samples, we compared BRCA1 expression in samples with and without BRCA1 deletions from each cancer type separately in differential expression analyses carried out using DESeq2\textsuperscript{52}. Cancer types were included if there were greater than 15 samples in total and if at least 3 of these samples harboured deletions. This effect was also measured across all samples pan-cancer adjusting for differences in expression between cancer types in the model. These analyses were repeated for BRCA2 expression. Effects on expression and the data behind them were displayed after variance stabilising transformation of the expression counts.

**Results**

**Large structural variants are a frequent source of BRCA1/2 disruption in HGSOC**

A variety of SVs were detected at the BRCA1/2 loci but large multi-megabase deletions spanning the entirety of BRCA1 or BRCA2 dominated. In all three cohorts, some deletions encompass more than 10% of chromosomes 17 or 13 though the majority are more focal (median BRCA1 deletion = 4.9Mb, median BRCA2 deletion = 6.2Mb) (Figure 1). Heterozygous deletions occur at similar rates at BRCA1 (16%) and BRCA2 (14%) overall, and at comparable rates between the similarly sized AOCS and SHGSOC cohorts (Supplementary Table 1). In 6/205 (3%) samples in the combined cohort, we observe large deletions at both BRCA1 and BRCA2 in the absence of short mutations at both genes. Permutation analyses reveal that BRCA1 and BRCA2 are deleted more than expected given the observed distribution of large deletions throughout the HGSOC genome (Supplementary Figure 3). This is consistent with selection for these events as has been reported for SNVs at BRCA1/2\textsuperscript{31} but we can not exclude the role of mutational bias in producing these enrichments of deletions. Inversions occur less often than deletions, but do occur in isolation in 6% of samples, and within
groups of large overlapping inversions in 5% of samples. In addition, we observe large duplications that span the entire length of either BRCA1 or BRCA2 in all cohorts (2% and 7% respectively) (Supplementary Table 2). Loss of heterozygosity was near ubiquitous at BRCA1 (202/205, 99%), of which 166 events were copy number neutral, and was present at BRCA2 in more than half of samples (118/205, 58%) of which 91 were copy number neutral. We observe similar genome-wide SV mutational spectra in each cohort despite the clinical differences among them: in particular AOCS represents chemoresistant/relapsed cases, while SHGSOC is composed mainly of samples taken before treatment. This suggests that large SVs predicted to impair BRCA1/2 function are a general feature of HGSOC evolution.

**Large deletions spanning BRCA1/2 are associated with lower gene expression**

We found that patients with a large deletion spanning BRCA1, in the absence of a GSM or SSM, had lower BRCA1 expression than those patients with no BRCA1 GSM, SSM or SVs (log2 fold change of no GSM/SSM/SVs versus a deletion only = 0.45, p-value=0.0093) (Figure 2). We also found that tumours with a large deletion spanning BRCA2 had lower BRCA2 expression than those without GSM/SSM/SVs at BRCA2 (log2 fold change in expression between no GSM/SSM/SV versus a deletion = 0.43, p-value = 0.037). In the analysis of BRCA2 expression, we included tumours with large deletions that also had GSM or SSM in the remaining copy, having shown that in our data BRCA2 expression is not significantly different in these tumours (Supplementary Figure 5). In spite of the unavoidable heterogeneity in tumour expression data among samples although variation in tumour purity was accounted for, the trends observed here are consistent with large BRCA1/2 deletions, reducing BRCA1/2 expression, though indirect mechanisms cannot be excluded.
Large deletions spanning BRCA1/2 contribute to HRD independently of pathogenic SNVs and indels

We examined the functional impact of all BRCA1/2 mutations detected across all cohorts using an established method, HRDetect\(^3\), which predicts HRD based upon genome-wide mutational spectra, and therefore provides a functional readout for the HRR pathway in tumours (Figure 3).

As expected, tumours with GSMs or SSMs in BRCA1/2, are more likely to have HR deficient tumours (HRDetect scores >0.7) than those tumours without GSMs, SSMs or SVs at these genes (GSM OR 6.9, 95% CI 1.8 – 33, p-value=2.3x10\(^{-3}\); adj. p-value= 3x10\(^{-2}\); SSM OR 25, 95% CI 3.2-1121, p-value = 1.7x10\(^{-4}\), adj. p-value = 2.3x10\(^{-3}\)) (Figure 3). Four samples with GSMs at BRCA2 demonstrated low HRDetect scores and accordingly showed no evidence for subsequent loss of the wild-type allele in the tumour which suggests that certain GSMs that are predicted to be disruptive are insufficient to generate HRD (Supplementary Table 3a).

The majority of samples (65%) with BRCA1/2 deletions were HRD (HRDetect score >0.7), though some deletions occur in tumours that also harbour short mutations (19/49). Since many of the samples with BRCA1/2 deletions lack short mutations (30/49, 61%), analysis of the effects of deletions independent of short variants was undertaken. The compound effect of deletions at both the BRCA1 and BRCA2 loci in the absence of short variants is particularly pronounced, demonstrating a significantly increased risk of HRD (OR 19, CI 2.4-896, p=1.3x10\(^{-3}\), adj p =1.7x10\(^{-2}\)) and consistently high HRDetect scores. Furthermore, compound deletions at both loci generate an OR that is comparable with other classes of HRD mutations known to have clinical importance, including the well-studied disruptive
BRCA1/2 short variants (Figure 3c,d)). Single deletions at either BRCA1 or BRCA2 do not consistently confer an increased risk of HRD in the absence of a BRCA1/2 short variant (Figure 3) though the analysis may be underpowered to detect small effects given the current sample size. The HRDetect scores for samples with these single deletions form a bimodal distribution for which we have been unable to find a defining characteristic for the difference, such as the length of the deletion, resultant level of gene expression or a background of whole genome doubling. The estimated effect that we observe of a single deletion at BRCA2 merits further investigation although it does not achieve statistical significance in our data (OR 2, 95% CI 0.37-10.3). Previous studies have identified rearrangement signatures associated with HR deficiency\(^3\). We observe an elevation in these signatures, particularly in the case of rearrangement signature 5, in samples with deletion at BRCA1/2, which is broadly consistent with the levels of elevation observed in the presence of short mutations at BRCA1/2 (Supplementary Figure 6). However, HRDetect incorporates additional genome-wide sources of information including the more powerful presence of indel microhomology leading to more accurate HRD prediction.

Beyond deletions the functional impact of other classes of SV, such as inversions or duplications, is less well studied. Half of the samples with only BRCA1 inversions bear an HR deficient signature which suggests that although in isolation their presence is not associated with HR deficiency these samples can show evidence of HRD perhaps via another unappreciated route (Figure 3). In contrast, only one of the samples with only BRCA2 duplications is HR deficient, which suggests potential for enrichment in HR proficient samples but this would need to be further explored in greater sample sizes.
Deletions are a frequent source of BRCA1/2 inactivation in repair deficiency

Samples across the combined cohort never had more than one short mutation across BRCA1 and BRCA2. This suggests that SSMs are not a mechanism for biallelic inactivation of a gene affected by a GSM. This is consistent with reports from a previous study of HGSOC\textsuperscript{31} (Supplementary Tables 3a,b). In contrast, of the HGSOC tumours with a GSM at BRCA1/2 predicted to cause HRD, we find that 11/32 (34\%) show evidence for an SV at the same gene which, may contribute to HRD if the SV occurs on the other allele (Supplementary Tables 2 and 3). We find that most of these somatic events (8/11 = 73\%) are large deletions, while two tumours possess more than one SV spanning the same gene as the GSM and one more shows evidence of somatic duplication. The importance of ‘second hit’\textsuperscript{33} mutations in tumours is well established\textsuperscript{34} but these data suggest that multi-megabase deletions have an under-appreciated role in this phenomenon in HGSOC. Across the three cohorts, 24\% (50/205) of patients have a disruptive short variant at either BRCA1 or BRCA2, and 30\% (15/50) of these patients also carry a BRCA1/2 deletion at the same locus. Also, it appears that SVs, including deletions, can occur at both BRCA1 and BRCA2 in the same sample. Large somatic deletions occur at both BRCA1 and BRCA2 in 13 samples and in 7 of these samples there is no short variant at either gene, although 1 sample had a hypermethylated BRCA1 promoter. These data suggest that large deletions and other SVs disproportionately contribute to biallelic inactivation in HGSOC, driven by the unusually high rates of structural variation seen in this cancer\textsuperscript{35}.

Integrative modelling reveals complex mechanisms underlying repair deficiency

We comprehensively modelled the effects of a range of genomic alterations at the BRCA1/2 loci on HRD, to investigate the relative importance of these features in explaining the
patterns of HRD observed. Given the relative sparsity of the data and the correlation between features we used a multivariable elastic net regularised regression model.

In addition to the previously reported impact of short variants at \textit{BRCA1/2} and \textit{BRCA1} promoter hypermethylation on HRD, large deletions at \textit{BRCA2} confer an increased risk of HRD (Figure 4). Furthermore, samples with double deletions, where deletions are found at both \textit{BRCA1} and \textit{BRCA2}, are more likely to be HR deficient. Importantly, the influence of these double deletions on HRD exceeds that of genome-wide large CNV loads and genome-wide SV loads. Also, large inversions at \textit{BRCA1} are independently associated with an increased risk of HRD. The functional impact of these events on the gene is currently unknown but this suggests that these events may either be markers for processes that impact the gene’s function or may even directly impact the function of the gene themselves. The model’s ability to predict HRD was good with a mean ROC curve AUC of 0.75, which although promising suggests that there are additional unknown sources of HRD.

We can explain the observed pattern of HRD by the presence of mutational or epigenetic defects at the \textit{BRCA1/2} genes in 81 out of 106 samples with predicted HRD (72 GSM/SSM/SV at \textit{BRCA1/2}, 9 with \textit{BRCA1} promoter methylation) but a further 25 samples with HRD remain unexplained. On further examination, we found that all of these samples harboured damaging GSMs and/or SSMs at other HR genes (defined by KEGG pathway annotation; Supplementary Tables 5, 6 and 7), motivating analysis of the potential roles of mutations at loci other than \textit{BRCA1/2} and their inclusion in an expanded model. However, we found no convincing evidence for a strong influence of mutations at other HR genes or
the combined expression of genes dysregulated in the presence of HRD (Supplementary Figure 7).

**HRD is associated with longer survival in the absence of disruptive short variants at BRCA1/2**

In HGSOC, while HRD as a result of GSMs and SSMs at BRCA1/2 is associated with response to platinum and PARP inhibition and improved survival, the relationship between HRD resulting from disruption of BRCA1/2 via other mechanisms is less clear. A higher probability of HRD is significantly associated with longer overall survival in our combined cohort (HR = 0.64, 95% CI 0.53–0.76 (per 1 standard deviation increase), p-value = 8.4x10⁻⁷) and this effect is only slightly attenuated by adjustment for patient age and tumour stage at diagnosis (Figure 5a). Notably, this effect persists (HR=0.67, 95% CI 0.56-0.84 (per 1 standard deviation increase), p-value=3.6x10⁻⁴) (Figure 5b) when we exclude the patients with BRCA1/2 GSM/SSM, who are already known to have longer survival. We see a similar effect when we examine the effect of HRD on progression-free survival (PFS) (HR=0.77, 95% CI 0.64 – 0.93 (per 1 standard deviation increase), p-value = 0.007) which also is robust to the exclusion of patients with BRCA1/2 GSM/SSM (HR=0.79, 95% CI 0.64-0.98 (per 1 standard deviation increase), p-value=0.03). Correspondingly, in all of these instances patients with HRD tumours (HRDetect >0.7) have longer survival times than patients with non-HRD tumours. The effects observed are consistent with the presence of HRD through mechanisms other than BRCA1/2 GSMs and SSMs affecting overall survival.

**Large deletions at BRCA1/2 are abundant in other cancer types and disrupt expression**
Cancers with other sites of origin vary in their level of structural variation. It is possible that large deletions may compromise BRCA1/2 function in these cancers also. The Pan-Cancer Analysis of Whole Genomes (PCAWG) consortium recently generated conservative consensus SV calls based upon WGS data across many tumour types but did not report specifically on SV patterns at BRCA1/2\(^36\). These data illustrate that large deletions (Figure 6a) (and other SVs (Supplementary Figure 8)) at BRCA1/2 are common across a variety of non-HGSOC cancer types, including in cancers also known to show evidence of HRD such as breast and prostate cancer. In addition, two rare tumour types show notably higher frequencies of BRCA1/2 deletions: chromophobe renal cell carcinoma (CHRCC) and leiomyosarcoma. Exploiting matched RNA-seq for N=735 of the PCAWG samples we found that BRCA1 and BRCA2 have significantly lower expression in those samples with deletions at BRCA1 and BRCA2 respectively, in comparison to in those samples without a deletion (log2 fold change of no BRCA1 deletion versus a BRCA1 deletion= 0.94, p-value=5.9x10\(^{-12}\); log2 fold change of no BRCA2 deletion versus a BRCA2 deletion= 0.6, p-value=2.9x10\(^{-6}\)) after adjusting for primary site. Furthermore, BRCA1 expression was consistently compromised within all cancer types with sufficient samples to test individually (Figure 6b,c).

**Discussion**

DNA repair deficiency in general and HRD in particular represent cancer cell vulnerabilities that have recently been exploited to exceptional patient benefit\(^{14,15,17,19–24,37}\). However, the understanding of the genomic mechanisms that give rise to HRD is incomplete and the identification of patients whose tumours are homologous recombination deficient remains inaccurate.
In the largest collection of HGSOC WGS data examined to date, with matched expression data for most of the 205 tumours included, we have revealed new insights into the genesis of HRD in HGSOC based upon genome-wide mutational spectra. We show that structural variation at BRCA1/2 in HGSOC is frequent and dominated by multi-megabase deletions which are significantly enriched at BRCA1 and BRCA2 relative to the rest of the HGSOC genome. Examining transcriptomic data for the same samples we have shown that large deletions overlapping BRCA1/2 are associated with lower BRCA1/2 expression, suggesting a direct impact of these deletions on gene function in many cases. Large deletions spanning BRCA1/2 contribute to HRD independently of short variants, and samples with compound deletions affecting both BRCA1 and BRCA2 generate the highest risk of HRD. The frequent inactivation of BRCA1/2 by large deletions in HGSOC is novel to our knowledge, and the original analysis of the AOCS cohort reported only one BRCA1/2 large deletion (>1Mb)\(^5\) (Patch et al (2015), Supplementary Table 4.2). The original TCGA cohort analysis did report frequent losses of the chr13q and chr17q chromosome arms (including the BRCA1/2 loci) based upon SNP microarray data\(^6\) (Bell et al (2011), Supplementary Table S5.1), but such data are known to generate high levels of false positives and negatives\(^38,39\) and these losses were not postulated to affect BRCA1/2 function. Thus previous assessments of SVs impacting the BRCA1/2 loci have been characterised by under-reporting, likely to be a result of the use of less sensitive algorithms tuned to detect smaller focal deletions\(^5\) as well as CNA estimates derived from SNP microarray data\(^5,6\) and exome-restricted sequencing data\(^6,40\). Other types of structural variation are less frequent but still evident, such as large inversions at BRCA1 and duplications at BRCA2. The impact of these categories of mutation on the function of the gene is less well studied but our data suggest that when BRCA1 inversions in
particular are considered together with the other mutational events in the tumour, their presence may aid prediction of HRD.

Our data also suggest a significant frequency of *BRCA1* and *BRCA2* loss by structural variation in a series of other cancers including both cancers known to suffer *BRCA1* and *BRCA2* loss due to SNVs or indels such as breast, pancreatic and prostate cancer as well as a number of cancers outside of this group including squamous cell lung cancer and cervical cancer. Perhaps most notably soft tissue leiomyosarcoma had a high incidence of large deletions at *BRCA2* (47%) and chromophobe renal cancers (CHRCC) had a high incidence of large deletions of both *BRCA1* (53%) and *BRCA2* (47%). CHRCC often undergoes concurrent deletion of both *BRCA1* and *BRCA2* as a result of whole chromosome arm losses as has been previously reported\(^4\) and trials of PARP inhibition as a therapy for renal cell carcinoma are ongoing\(^4\). The fact that across these cancer types, large *BRCA1* and *BRCA2* deletions were associated with loss of gene expression suggests functionality is lost and that strategies to detect these genomic events and trials of PARP inhibition should also be considered in these patients.

Finally, we have constructed an integrated model of HRD in HGSOC, including a large variety of mutation and expression-based variables across the combined cohort. This model supports an independent role for structural variation at *BRCA1/2* in HRD and highlights the diversity of routes that tumours may follow to reach HRD. Given this diversity, and the substantial fraction of samples where HRD is detected in the absence of any detectable *BRCA1/2* mutations, we conclude that the direct detection of HRD in HGSOC using genome-wide sequencing data is a valuable addition to the search for inactivating mutations in HR
pathway genes. This is likely to be the case for other cancers showing evidence for HRD, such as uterine, lung squamous, oesophageal, sarcoma, bladder, lung adenocarcinoma, head and neck, and gastric carcinomas. The variety of events sufficient for a tumour to develop HRD is not well understood, but recent studies suggest that there is selective pressure for biallelic inactivation leading to HRD in cancer types with predisposing germline variants in the HR pathway, such as breast, ovarian, pancreatic and prostate cancers.

One of the key challenges in studies of this type is deciding upon a ‘gold standard’ test of HRD. Current functional, clinical and molecular tests all have advantages and disadvantages. The limitations of HRDetect that we use here include that it was developed and trained using breast tumour data and is predicated on BRCA1/2 deficiency arising from SSV disruption and promoter methylation, rather than any form of disruption to any HR gene. Although in the context of the current study, of BRCA1/2 disruption by SV, the latter is of less importance. All current genomic HRD tests are further limited to demonstrating that HRD once existed in the evolution of a tumour, and are blind to the restoration of HR by events such as secondary mutations, hypomorphic HRD variants and epigenomic changes.

There is an urgent clinical need to better understand the processes that give rise to both BRCA1/2 loss and more broadly contribute to HRD. Our study demonstrates that BRCA1/2 loss by structural variation may have a comparable impact on HRD and patient survival to short variants at BRCA1/2. Furthermore, these events are not specific to HGSOC, they are abundant, they compromise gene expression and are likely to be functionally important in other cancer types including in those types where HRD has been previously identified. However, these variants are unlikely to be detected by sequencing methods currently
employed in the clinic. A change in sequencing approach to identify all BRCA1/2 loss may be required to maximise the potential of PARP inhibition.

Data availability

Previously published WGS and RNA-seq data that were reanalysed here are available via EGA at accession code EGAS00001001692 (ICGC PCAWG). WGS, RNA-seq and clinical data from the Scottish cohort (SHGSOC) will be made available via EGA at accession code EGAS00001004410. Other supporting data have been provided in the Supplementary Tables.

Code availability

All code will be made available at:

https://github.com/ailithewing/Structural_variants_BRCA1_2_HRD_inHGSOC.

Figures

Figure 1: Abundance, location and size of structural variants overlapping BRCA1/2 in three HGSOC cohorts. a) Alignment of structural variants overlapping BRCA1 across the AOCS, TCGA and SHGSOC cohorts with breakpoints marked in grey according to their position on chromosome 17. Location of BRCA1 marked by a blue line with deletions (blue), duplications (orange) and inversions (purple). b) The distribution of sizes of structural variants (Mb), overlapping BRCA1 across all cohorts. c) Alignment of structural variants overlapping BRCA2 across the three cohorts with breakpoints marked in grey according to their position on chromosome 13. Location of BRCA2 marked by a blue line. d) The distribution of sizes of structural variants (Mb) overlapping BRCA2 across all cohorts with deletions (blue), duplications (orange) and inversions (purple).
Figure 2: Structural variation and expression of BRCA1/2 in the combined HGSOC cohort. a) Expression of BRCA1/2 (variance stabilising transformed RNA-seq counts) across samples ordered from lowest to highest expression. Median BRCA1/2 expression is indicated by a black dashed line. Sample bars are coloured by BRCA1/2 mutational category. b) Boxplot of BRCA1/2 expression for each category of BRCA1/2 mutation. The BRCA1 deletion category is split into those samples with SNVs and deletions and those with only deletions as their expression is significantly different (Supplementary Figure 5a). This is not the case for BRCA2 so all samples with deletions are considered together to maximise the available sample size (Supplementary Figure 5b).
Figure 3: *BRCA1*/*2* mutation classes and repair deficiency in three HGSOC cohorts. a) Predictions of HRD for three large cohorts of HGSOC coloured by *BRCA1*/*2* structural variant status and outlined by *BRCA1*/*2* mutation status. Categories of mutation include GSVs and SSVs. Categories of structural variation include deletions, duplications, inversions and complex overlapping combinations thereof as formally described in the methods and absence of structural variants at *BRCA1*. The HRDetect scores range from 0, least likely to be HR deficient to 1, most likely to be HR deficient. The red dashed line represents the threshold of 0.7 representing HRD. b) The number of HRD tumours with different categories of *BRCA1*/*2* short variant(s), deletions or non-deleting SVs. c),d) The increase in log odds ratio of HRD (HRDetect score > 0.7) associated with different categories of mutation and structural variation at *BRCA1*/*2* in comparison to the frequency of the reference category where samples lack evidence of *BRCA1*/*2* inactivation (GSV, SSV, SV). All categories apart from the BRCA1 promoter methylation category itself also exclude tumours with BRCA1 promoter methylation where this is known (TCGA and AOCS). ORs are defined using Fisher’s Exact tests for enrichment. Error bars represent 95% confidence intervals. Mutually exclusive categories of mutation examined include GSV only, SSV only, the presence of a deletion at one or both genes without a GSV or SSV, the presence of a short variant together with deletion of one or both genes, non-deleting SVs in samples without short variants or deletions, samples with *BRCA1* promoter methylation and no mutational *BRCA1*/*2* deficiencies.
Figure 4: Integrative modelling of repair deficiency in HGSOC. a) Median effect sizes of genomic features selected to predict HRD, using elastic net regularised regression on 100 training/test set splits. Model performance was measured for each split and average AUC = 0.75. Binary mutational status variables (e.g. presence/absence of BRCA1 somatic SNV) were included as factors and continuous variables were standardised to allow comparisons between variables. b) Distributions of effect size for each variable on HRD (log odds) in each training/test set split. Variables in red are selected for inclusion by the model in more than half of the training sets.
Figure 5: Predicted HRD is associated with patient survival in the absence of short variants at BRCA1/2. a) The effect of HRD on overall survival time after diagnosis (in days) in HGSOC. (N (events) =190 (144)). b) The effect of HRD on overall survival time after diagnosis (in days) in HGSOC patients without BRCA1/2 GSV/SSV. (N (events) =145 (113)). c) Forest plot showing the effects of HRD on overall and progression-free survival, unadjusted and adjusted for age and stage at diagnosis in a multivariable model. Estimates are also shown with tumours with SNVs/indels at BRCA1/2 excluded. Kaplan-Meier plots compare survival times between HR deficient and HR proficient patients as defined by HRDetect score above and below 0.7. Hazard ratio estimates (on a log scale) are taken from Cox proportional hazards models and correspond to a 1 standard deviation increase in HRDetect score, stratified by cohort and adjusted for age and stage at diagnosis.
Figure 6: Deletions at BRCA1/2 in other cancer types and their impact on expression. a) The proportion of samples with deletions at BRCA1, BRCA2 or both, by primary site in PCAWG. b) BRCA1 expression in tumours with and without deletions at BRCA1 coloured by primary site. c) BRCA2 expression in tumours with and without deletions at BRCA2 coloured by primary site. Gene expression visualised in variance stabilising transformed (VST) counts. P-values are from differential expression analyses conducted using DESeq2 for each primary site separately and are adjusted for multiple testing using the Benjamini-Hochberg approach. Only sites with at least 15 samples in total and at least 3 samples with a deletion at the gene in question were included.
