Novel phenotype of mouse spermatozoa following deletion of nine β-defensin genes

Julia R Dorin

β-defensin peptides are a large family of antimicrobial peptides. Although they kill microbes in vitro and interact with immune cells, the precise role of these genes in vivo remains uncertain. Despite their inducible presence at mucosal surfaces, their main site of expression is the epididymis. Recent evidence suggests that a major function of these peptides is in sperm maturation. In addition to previous work suggesting this, at the MRC Human Genetics Unit, Edinburgh, has shown that homozygous deletion of a cluster of nine β-defensin genes in the mouse results in profound male sterility. The spermatozoa derived from the mutants had reduced motility and increased fragility. Epididymal spermatozoa isolated from the cauda region of the homozygous mutants demonstrated precocious capacitation and increased spontaneous acrosome reactions compared with those from wild-types. Despite this, these mutant spermatozoa had reduced ability to bind to the zona pellucida of oocytes. Ultrastructural examination revealed a disintegration of the microtubule structure of mutant-derived spermatozoa isolated from the epididymal cauda region, but not from the caput. Consistent with premature acrosome reaction and hyperactivation, spermatozoa from mutant animals had significantly increased intracellular calcium content. This work demonstrates that in vivo β-defensins are essential for successful sperm maturation, and that their disruption alters intracellular calcium levels, which most likely leads to premature activation and spontaneous acrosome reactions that result in hyperactivation and loss of microtubule structure of the axoneme. Determining which of the nine genes are responsible for the phenotype and the relevance to human sperm function is important for future work on male infertility.

Keywords: acrosome reaction; antimicrobial; capacitation; epididymis; sperm; β-defensins

BACKGROUND TO β-DEFENSINS

β-defensins are cationic peptides with a canonical six cysteines in their mature secreted form, which were first isolated as antimicrobials, and their presumed function is in host defense. The β-defensin gene family consists of 40 family members at five gene loci in humans and more than 50 genes over four loci in the mouse. The main cluster is on chromosome 8 in both humans and mice with 10 and 31 β-defensin genes, respectively. In humans, seven of the chromosome 8 genes lie at two distinct loci approximately 5 Mb apart as highly copy number variable (CNV) clusters, which vary between 2 and 7 copies per genome. It is, therefore, possible that phenotypic change may be present owing to reduced or increased copy number. Increased copy number above the mean diploid number of 4 has been associated with an increased risk of psoriasis. It is evident that the evolutionary history of this gene family is complex with evidence for both rapid positive as well as negative selection. Despite recent evidence of an increasing functional repertoire of β-defensin peptides, which includes involvement in pigmentation, immune cell attraction and immunomodulation, the physiological function of mammalian β-defensins in vivo remains uncertain.

Previous work on the importance of β-defensins in sperm function

Interestingly, β-defensins are highly expressed under normal conditions in different segments of the epididymal epithelium and are likely to be secreted into the lumen, and some have been shown to be present on the plasma membrane of sperm cells. It seems likely therefore that they are involved in reproductive function, and a few studies over the last decade have suggested that β-defensins influence sperm maturation. The rat β-defensin Bin1b (SPAG11 or EP2) has been shown to induce immature and immotile spermatozoa to become progressively motile in vitro. In addition, the β-defensin DEFB126 on chromosome 20 has recently been linked to the ability of human spermatozoa to penetrate hyaluronic acid gel (which mimics the consistency of female cervical secretions). Men homozygous for a frameshift mutation in DEFB126 are not infertile but have reduced the chance of pregnancy in the first year. DEFB126 is quite different from other β-defensins, as it has an extensive C-terminal tail containing O-linked glycosylation sites that are not seen in other defensins. It is presumed that this glycosylation is important for its function. Additionally, in the rat incomplete knockdown of Defb15 suggests that this peptide influences sperm motility, but apparently not the capacitation process or the acrosome reaction (AR). Most recently, low levels of human β-defensin 1 (hBD1) have been found in spermatozoa from infertile men with low sperm motility. This work also shows that the affected spermatozoa have a defect in bacteriocidal activity, and this can be corrected by addition of exogenous peptide.

GENERATION OF A β-DEFENSIN GENE KNOCKOUT IN THE MOUSE

The mouse is a good model of certain aspects of innate immunity although...
many of the multigene families have species- or environment-specific clades, and the β-defensin gene family is no exception. Some of the human defensin genes have single-gene orthologues in the mouse whereas some have several paralogues. Single-gene deletion can result in an obscure phenotype, as functional redundancy in gene families can play a significant role in obscuring functional roles. Some years ago my laboratory, and others created mice that were deleted for Defb1 (the mouse orthologue of the gene for hBD1) and the homozygous animals had a subtle gross phenotype: a defect in bacterial clearance following infection (the second cysteine of the motif is missing)(see Table 1). Defb50 has poor antimicrobial activity in its oxidized form, but even this improves under reduced conditions. These results support deletion of the expression of these antimicrobials from the homozygous mice, there was no indication that the mutant mice had increased inflammatory profile under normal specific pathogen-free animal housing conditions.

**INFERTILITY PHENOTYPE OF MUTANT DEFBΔ9/DEFBΔ9 MICE**

The mice that were initially produced as heterozygotes from chimeric animals derived from blastocysts injected with the ES cell gene-targeted lines and mated to C57Bl/6 females and were then inter-crossed to generate homozygous deletion mice. These mutant animals contained a high contribution of genetic background from the 129/Ola E14 ES cells, and the homozygous males at this point were fertile but showed a reduced ability to impregnate wild-type CD1 females. The male deletion mice sired equivalent numbers of litters but a low number of pups per litter. When the mice were inbred to four backcross generations onto C57Bl/6, the male homozygotes generated were completely infertile although homozygous females had normal fertility.

**DefbΔ9/DefbΔ9 spermatozoa are fragile**

In an effort to ascertain if the defect in fertility was due to sperm production, sperm numbers released from excised cauda region of the epididymis were assessed, but they were not significantly different between mutant males and wild-type C57Bl/6 male mice. In addition, tissue sections along the length of the epididymis were histologically normal, with evidence of comparable numbers of spermatozoa in the lumen. However, we did observe that isolated spermatozoa dropped onto a microscope slide were more fragile, as the number of headless tails counted was significantly higher in the mutants than in the wild-type animals.

**DefbΔ9/DefbΔ9 spermatozoa have reduced motility and spontaneous acrosome reactions**

In collaboration with Prof. Chris Barratt (University of Dundee), we used computer-assisted sperm analysis to determine the total and progressive motility of the spermatozoa from mutant and wild-type littermates. The sperm cells were very gently isolated from the cauda region of excised tissue to reduce any trauma to them, but nevertheless those from the mutants had a very obvious and significantly lower percentage of progressive motility both before capacitation, at zero time, and after capacitation.

### Table 1: Amino acid sequence in single letter format, of the β-defensin peptides encoded by the genes deleted in the DefbΔ9/DefbΔ9 mice. The cysteine residues are emboldened in the mature peptide sequences and are lined up for best fit with dashes indicating where spaces have been introduced to facilitate this. The first exon of these two exon genes is in bold while the second exon is not. Signal sequence cleaved predicted by ExPAsy proteomics tool

induction, at 90 min. Further work demonstrated that the deletion mouse-derived spermatozoa had a higher percentage of spontaneous acrosome reactions (ARs) at time 0 and also at 90 min. The presence of an intact acrosome was measured by several different techniques. The first was the ability of spermatozoa to bind a fluorescently-labelled Pisum sativum (PSA) lectin that interacts with the glycocalyx carbohydrate molecules of the acrosome. Secondly, an antibody to zonadhesin was used to demonstrate if binding was increased owing to loss of the acrosome revealing the zonadhesin epitope that binds the antibody. Finally, acrosomal integrity following Coomassie Blue G250 staining of fixed sperm cells was determined since acrosome-reacted spermatozoa lack G250 staining. By all these criteria, the spermatozoa from the mutant males had significantly increased level of spontaneous ARs. The level present upon isolation was maximal, as it appeared to be equivalent to the level evident in wild-type mouse sperm incubated for 90 min in capacitation medium.

Capacitation is the process by which spermatozoa in close proximity to the egg in the female reproductive tract will undergo physiological and membrane changes that enable fertilization of the oocyte. No direct procedure is available to determine capacitation status, but AR induction provides information on the rate of capacitation. Therefore, the extent of sperm capacitiation can be evaluated indirectly by measuring the number of cells without an acrosome (using PSA binding to indicate acrosomal presence) following induction of the AR, as only capacitated cells can undergo this process. Capacitation of spermatozoa isolated from the cauda epididymis was induced by the calcium ionophore A23187. The DefbΔ9/DefbΔ9-derived spermatozoa displayed the maximal percentage of capacitation immediately after exposure to the drug. This level did not increase after 90 min, whereas the status of sperm capacitiation for wild-type spermatozoa increased from 6% to 23% over this same period.

**DefbΔ9/DefbΔ9 sperm cannot bind to unfertilized eggs**

As the mutant-derived spermatozoa were both acrosome reacted and capacitated, we tested if they were able to fertilize eggs by using a sperm-egg binding assay with wild-type eggs. The number of wild-type spermatozoa that could bind to the cumulus-free eggs from superovulated CD1 females was around 20 per egg after 45 min, but only negligible numbers of mutant spermatozoa were bound. Recent studies in the mouse have shown that spermatozoa that have undergone the AR can penetrate the zona pellucida (ZP), although this is not an efficient process. As the mutant-derived spermatozoa were both acrosome reacted and capacitated, we tested if they were able to fertilize eggs by using a sperm-egg binding assay with wild-type eggs. The number of wild-type spermatozoa that could bind to the cumulus-free eggs from superovulated CD1 females was around 20 per egg after 45 min, but only negligible numbers of mutant spermatozoa were bound. Recent studies in the mouse have shown that spermatozoa that have undergone the AR can penetrate the zona pellucida (ZP), although this is not an efficient process, but the mutant phenotype is reminiscent of demembranated sperm cells that have undergone hyperactivation following capacitation. In this situation, spermatozoa that are stimulated with calcium to increase tail movement can display disintegration of the axonemal filaments. The mutant defensin-deleted spermatozoa may have such a fragile membrane that the microtubule structure is subject to disorganization.

The fact that defensins have diverse receptor-binding activity may explain the increase in calcium seen in the mutant sperm cells. It is possible that normally one or more of the defensins can block a calcium channel such as CatSper. Indeed, the defensin-like molecule MsDef1 from Alfalfa seeds has been shown to have the ability to block mammalian L-type calcium channel activity. There is evidence to suggest that seminal fluid has components that suppress calcium transport activity until the membrane remodelling occurs during capacitation when the spermatozoa are in an appropriate region of the female reproductive tract. Perhaps β-defensins normally in the glycocalyx are part of this inhibitory process, protecting against inappropriate activation of spermatozoa in the epididymis, a site where sperm cells are mature but not appropriately located for fertilization.

**UNANSWERED QUESTIONS REMAIN**

These data show a clear function of one or more of the β-defensins in the deleted cluster being essential for sperm function, but it is not known if the sterility of the male reproductive tract is compromised. Is loss of genes with in vitro antimicrobial function important in vivo for infection defense? What of the immunomodulatory activity of defensins: is this of relevance in the epididymis? At the moment, we do not know which of the nine defensins genes are responsible for the unique fertility phenotype. It is suggested that epididymal maturation of sperm cells more likely occurs in the caput or corpus of the epididymis rather than the cauda. The defensins present in the deletion have been shown to be present in distinct regions of the epididymis. Defb15, 35 and 13 are expressed in the upper region (segments 1, 5 and 6, respectively), whereas Defb2, 9, 10, 11 and 50 expression is focused in segment 8 of the cauda region, while Defb1 is expressed in the penultimate segment of the epididymis.
Using mass spectrometry, we have only been able so far to detect Defb2, Defb11, and Defb15 on isolated wild-type cauda spermatozoa. Rat Defb15 has been reported to bind to the acrosomal region of caput sperm cells, and incomplete knockdown results in rats with reduced sperm motility, but no defect in capacitation or AR. Interestingly, Defb15 has an extended carboxyl tail containing an extra cysteine and six potential serine or threonine residues that would support O-linked glycosylation. O-linked glycosylation is considered a key feature of the function of DEFB126 in human spermatozoa, and it also seems to affect the ability of spermatozoa to move in a viscous hyaluronic acid used as a cervical mucus substitute. There is a parologue of Defb15 not within the deleted region, and this gene (Defb34) is only three amino acids different from Defb15 in the mature segment of the peptide, which may make Defb15 a less likely candidate to affect spermatozoa.

It may be that deletion of a single-gene might not demonstrate a strong enough phenotype for it to be easily recognized. The three human orthologues to Defb15, Defb35 and Defb13 (DEFB106, DEFB105 and DEFB107, respectively) are on the chromosome 8p23.1 highly copy number-variable block. In primates, protection against loss of fertility from mutation might be a selective advantage that allows the increase in copy number of these genes to be maintained. We have systematically knocked out the genes in the deletion using Crispr/Cas9 technology of pronuclear injection into C57BL6/eggs, and determination of fertility and sperm phenotype in these single-gene KOs is currently ongoing.

CONCLUDING REMARKS

For the first time, we show here that β-defensin antimicrobial peptide genes have a profound effect on sperm function in vivo, and this is manifest in the Defb15−/− mice by increased intracellular calcium, precocious capacitation, increased spontaneous ARs, and microtubule destabilization, which results in lack of motility and profound infertility. This provides evidence for β-defensins being essential for appropriate control of intracellular calcium and regulation of the AR. It is most likely that their loss results in destabilization of the sperm membrane that allows calcium influx and microtubule disruption. This improved understanding of the function of these antimicrobial peptides in mouse leads the way to investigating the role of the human orthologues in sperm function and fertility, and opens the possibility of the development of novel contraceptives with additional role of the human orthologues in sperm function and fertility, and opens the possibility of the development of novel contraceptives with additional expression for the initiation of sperm maturation. Nat Cell Biol 2004; 6: 458–64.
