ABSTRACT

Estimates for lifetime costs of wave energy arrays are difficult to obtain due to the uncertainty surrounding weather windows and failure rates for wave energy converters (WECs). An operations & maintenance (O & M) simulation tool has been used to assess the sensitivity of WEC failure rates on the profitability of a wave farm, with the Pelamis P2 device used as a case study. Two offshore wave energy sites in the UK have been characterised and presented in terms of accessibility for marine operations and power generation. It was found that a wave farm at one site would incur higher costs due to vessels having to wait longer for suitable weather windows. This was balanced by higher generated revenue, showing how the tool can be used to support strategic planning and site selection. The results identify the sensitivity to failure rate estimations for different components, helping target future work to reduce uncertainties and costs. The results highlight the need for WEC developers to collaborate closely with component manufacturers in order to design the best device possible for the challenging marine environment. Collaboration enables more realistic failure rate estimates to be obtained, leading to better understanding of the operational costs for commercial wave energy farms.

1. Introduction

The wave power sector has potential to be a major contributor to global renewable energy generation. At a national level, the total power capacity of wave energy projects in UK waters could potentially reach 13 GW in the future (Boud, 2012). Globally, up to 95 GW of wave energy devices could be installed in the world's seas and oceans (Gunn and Stock-Williams, 2012). However, the wave energy sector has not yet seen the development of commercial-scale arrays. Several different device concepts have been considered since the 1970s. This includes seabed-fixed devices (e.g. 'Oyster', 'Wavestar'), as well as floating designs (e.g. 'Edinburgh Duck', 'Pelamis'). Significant advances have been made in terms of understanding the hydrodynamic behaviour of wave energy devices in the marine environment, as well as in other areas such as estimating power capture (Borthwick, 2016). However, the early part of this decade has seen several of the major companies in

the sector go out of business. Interest in tackling the wave energy challenge is still strong, with governments around the world funding initiatives such as Wave Energy Scotland (Highlands and Islands Enterprise, 2016) and the Wave Energy Prize (EERE, 2017). A recent report by the European Commission (Magagna et al., 2016) states that up to 37 MW of wave energy projects could be operational within the European Union (including the United Kingdom) by 2020.

One of the key barriers to commercialisation of the wave energy sector is the high cost of energy relative to other forms of renewables. Wave energy is estimated to cost up to \$500US/MWh (£380/MWh) at present, compared to approximately \$200US/MWh (£150/MWh) for offshore wind (World Energy Council, 2013). For the developers of wave energy converter (WEC) technology to attract private investment, it is vital that they obtain realistic estimates for the levelised cost of energy (LCOE) based on a holistic engineering approach.

Operations and maintenance (O & M) will account for a significant

amount of the total costs of any offshore renewable energy development. In the offshore wind industry, O & M costs account for approximately 20% of the total costs of wind farms (BVG Associates, 2013). Estimates for this operational expenditure (OPEX) are difficult for WECs due to the relatively small amount of experience gained in the sector. However, estimates can be obtained through the use of O & M simulation tools. These have been used widely in the offshore wind industry over the years for both cost estimation and operations planning (Hofmann, 2011; Pahlke, 2007). They can also provide a clear picture of the O & M strategy considerations necessary to ensure smooth operation of wind farms, as demonstrated by Scheu et al. (2012) and Douard et al. (2012). Building O & M simulation tools for wave energy has significant potential in developing wave energy projects (Walker et al., 2013) and providing feedback into the design of devices (Martin et al., 2016).

The limited operational experience of wave energy converters in comparison to offshore wind turbines means that some estimates of wave energy OPEX simply assume a percentage of capital expenditure (CAPEX), as demonstrated by O'Connor et al. (2013). Very few examples of simulation tools modelling detailed O & M strategies of wave energy arrays have been published. One model presented by Abdulla et al. (2011) takes the case study of Aquamarine Power's 'Oyster' WEC and uses a Monte Carlo approach to simulate the occurrence of faults on the device. The study assesses the availability of the WEC but does not analyse costs. Another example is the model representing the Wavestar device, presented by Ambühl et al. (2015), where failure rate data from the offshore wind industry is translated to the WEC. A 'damage model' is included to account for fatigue of structural components. Commercially-available simulation tools for wave energy arrays, such as ForeCoast Marine (JBA Consulting, 2015) and MERmaid (Mojo Maritime, 2016), are focussed on accessibility and marine operations planning at present, rather than on obtaining estimates of OPEX. A European funded project, DTOcean, has produced an open-source suite of tools to allow developers of WEC technology to begin planning arrays (Weller et al., 2015). The project includes a lifecycle logistics work package which may help assess the O & M strategy of a wave energy farm, if adequate inputs to the tool can be provided (Teillant et al., 2014).

One of the key inputs required to obtain realistic estimates and scenarios from an O & M simulation tool is failure rate data. This is becoming less of a problem in the offshore wind industry due to the relatively large amount of operational data available to both academics and industrial researchers. Carroll et al. (2015) draw on a population of over 2000 wind turbines to undertake an analysis on reliability of different generator types. The significant amount of available data for offshore wind turbines has led to the creation of the SPARTA (System Performance, Availability and Reliability Trend Analysis) project; "a database for sharing anonymised offshore wind farm performance and maintenance data" (ORE Catapult, 2016). SPARTA was inspired by the OREDA handbook, first created in 1981, which has contributed to improved safety and cost effectiveness in the oil and gas industry (OREDA, 2015). A similar reliability database for wave energy is not possible at present, in part due to the large variety of WEC concepts currently being explored.

Obtaining reliability data for WECs is particularly challenging due to the paucity of full scale testing in open sea conditions (Thies et al., 2012). Destructive testing on generic components such as mooring lines is an extremely useful activity for reducing the uncertainty for failure rates (Weller et al., 2014). Any other WEC components are device-specific, however, and therefore require testing to be undertaken by the developer themselves. Such testing can be time consuming and expensive, making it unattractive to WEC developers with tight financial constraints (Wolfram, 2006). As a result, destructive testing is usually only considered necessary for key components such as hydraulic ram cylinders (Rühlicke and Haag, 2013).

Many off-the-shelf components such as hydraulic seals are supplied

by the manufacturer accompanied by expected failure rates (Voith, 2016). This data may not be accurate for WECs, however, as the components are being used in a different way and in a different environment than their design specifications (Thies et al., 2012). In reality, the best source of reliability information at this early stage of the wave energy sector's development is the expert judgement of the engineers involved. There is a significant amount of uncertainty surrounding failure rates obtained in this manner and this needs to be accounted for when used in O & M tools for estimating OPEX and availability of a wave farm.

Weather data is also a key requirement of an O & M model in order to evaluate so called 'weather windows'; periods when the devices can be accessed by vessels and maintenance crew. The weather conditions defining these windows generally come through operator experience as well as vessel specifications (O'Connor et al., 2013). O & M tasks for a wave farm should be scheduled for periods when accessibility is highest and expected revenue is at a minimum (Walker et al., 2013), though this may not always be possible due to unexpected failures. Weather data is also required for yield estimation. Higher temporal and spatial resolution, as well as the proximity of source weather data to a proposed site, will improve the accuracy with which an O & M tool can represent weather conditions, resulting in a more robust estimation of OPEX costs and farm availability.

This study addresses site characteristics affecting accessibility and power performance, and uncertainty surrounding failure rate estimates for wave energy converters. The study makes use of a Monte Carlo-based O & M simulation tool, whereby failure rates are used to simulate the occurrence of faults on a machine. A case study based on the second-generation Pelamis WEC has been used due to the significant amount of experience gained during a testing programme achieving over 11,000 grid connected hours. The study aims to demonstrate the model as an effective tool for budgeting and planning of a wave energy array. It also highlights the ability of the tool to support targeting work priorities for developing wave energy technologies.

The methodology of this study, including the model inputs and functionality, is described in Section 2. The model's base case scenario is detailed in Section 3, along with the characteristics of two selected sites. The results of the sensitivity analysis are presented and discussed in Section 4. The main conclusions of the study are highlighted in Section 5, before further work is suggested in Section 6.

2. Methodology

The O & M tool used in this study is focused on the Pelamis P2 device (Fig. 1), rated at 750 kW. The tool was developed initially in 2007 by Pelamis Wave Power. The software has since been upgraded over the course of a partnership with the Industrial Doctoral Centre for Offshore Renewable Energy (IDCORE).

2.1. Pelamis O & M strategy

The operations and maintenance phase of wave energy converters needs careful consideration for arrays of the devices to become economically viable. Lessons can be learnt from the more advanced

Fig. 1. One of the two Pelamis P2 machines operating at EMEC in 2012 (Pelamis Wave Power).

offshore wind industry, as well as the recent deployments in the tidal stream sector. Many of the WEC concepts studied in recent years involve a floating or buoyant design with the maintenance strategy being to undertake repairs and inspections offsite using low-cost vessels (e.g. Carnegie Clean Energy's 'CETO' heaving-buoy device and Wello Oy's rotating-mass 'Penguin' machine). This is widely acknowledged as the best method of accessing wave energy converters, with even previously seabed-fixed WECs changing their design to incorporate the low-cost vessel approach in an effort to reduce downtime (Davidson, 2012).

The P2 device was designed with a 'plug in and play' system, whereby the machine could be installed and removed from its electrical and moorings connection point remotely using controllers on board the installation vessel. The maintenance strategy was to remove the WEC from its offshore location to the safety of a sheltered harbour where spare parts could be readily available and the persistence of weather conditions is not a concern. No maintenance was to be carried out whilst the device was offshore, regardless of weather conditions. A P2 installation operation could be carried out in less than an hour once the machine was on site, using two small, low cost, multi-purpose workboats as shown in Fig. 2. A removal operation could be carried out 'in a matter of minutes' (Yemm et al., 2012) and in rougher seas using only one workboat.

2.2. Model overview

The model replicates the O & M strategy of the Pelamis device by taking inputs of failure rate estimates, repair parameters and weather data in order to simulate operations and maintenance over the lifetime of a wave energy farm. The inputs to the O & M tool have come from the expert judgement of the engineers involved in the Pelamis endeavour. Outputs, including availability, revenue and operational expenditure, are produced for each year and for every WEC in the wave farm. Fig. 3 summarises the inputs and outputs of the O & M tool. The 'maintenance manager' in Fig. 3 represents the programming element of the O & M tool, where the lifetime of the wave energy array is simulated using a Monte Carlo approach at each time step. This is explained further in Section 2.4.

2.3. Model inputs

2.3.1. Failure rates

Failure rate data is one of the key inputs required to run an O & M simulation tool. Between 2008 and 2014, the two P2 machines achieved over 11,000 h of grid connection at the European Marine Energy Centre (EMEC) in Orkney. Initial estimates for the P2 device (prior to their deployment) came from four main sources; i) manufacturers' specifications for off-the-shelf components, ii) a US military handbook on reliability prediction (US Department of Defense, 1991), iii) destructive testing on several components (Pelamis Wave Power, 2013), and iv) the limited operational experience with the Pelamis prototype and P1 devices. These estimates were updated over the course of the P2 testing programme, as staff at Pelamis Wave Power learnt more about their device through operational experience. The

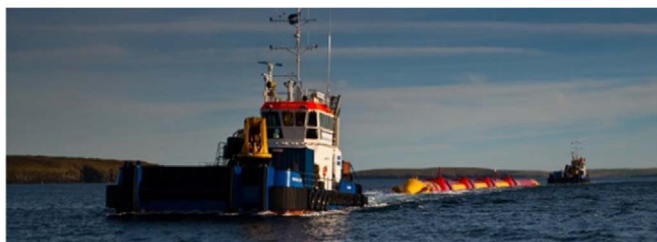

Fig. 2. A Pelamis P2 device being towed for installation at EMEC in 2012 (Pelamis Wave Power).

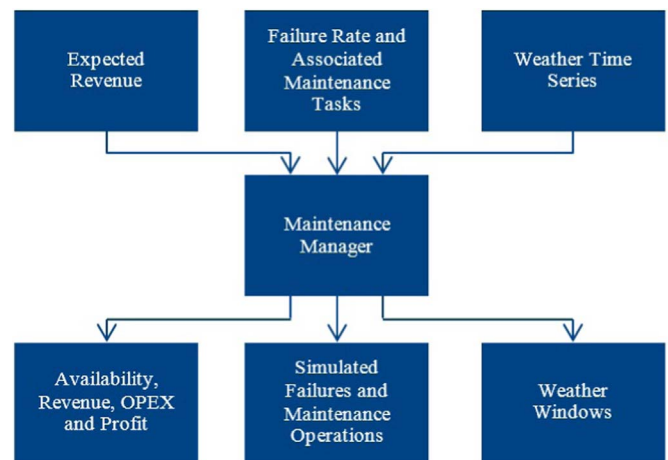

Fig. 3. O & M tool flowchart of key inputs and outputs (Gray et al., 2014).

failure rate inputs to the O & M tool were last reviewed and updated in October 2014. It should be noted that these failure rate inputs are fixed values, and therefore do not take into account early 'infant mortality' failures or degradation of components over time. A more complex and realistic representation of failure rates can be incorporated into future O & M tools by adopting a Weibull curve approach, as described by Thies et al. (2012).

2.3.2. Maintenance parameters

The components and subsystems of the P2 device are represented in the O & M tool by placing every potential failure into one of sixteen different fault categories, shown in Table A.1 (section 9). This allocation was undertaken using a Failure Modes and Effects Analysis (FMEA) to identify the overall consequence of every failure. Each category has a failure rate and associated maintenance parameters, such as power loss, parts cost and time to repair. The fault categories are classified as either major, intermediate or minor faults, depending on the severity of these associated parameters. A fault category may be made up of several failures that have a similar consequence, but may require different levels of repair. Therefore, the values for the failure rates and maintenance parameters provided to each fault category are the mean values when all the different failures represented in that category are considered.

2.3.3. Weather data

A time series of weather conditions containing significant wave height (Hs), wave energy period (Te) and wind speed is supplied to the tool. A time series of any length can be generated by a Markov-based weather model which has been developed for the O & M tool. It takes an input of hindcast data in order to generate a synthetic time series that displays enough variance to replicate both 'good' years and 'bad' years, yet shows the same seasonal trends as the input data. To achieve this, the three parameters in the hindcast dataset are placed into 'bins' and combined as 'sea states'. The 'bins' range from 0.25 to 9.75 m in steps of 0.5 m for Hs, from 3 s to 15 s in steps of 2 s for Te, and from 2.5 kts to 47.5 kts in steps of 5 kts for wind speed. The hindcast dataset is then separated by month in order to ensure seasonal variability. At each time step, the next 'sea state' is recorded, enabling a probability transition matrix to be created for each monthly dataset. It is then possible to generate a new time series using the fundamental Markov property that the weather conditions at the present time step depend solely on the conditions at the previous time step. Validation and further details about the functionality of the Markov Chain Model can be found in (Gray et al., 2015). This method has been developed to enable the O & M tool to incorporate the learning gained during real sea testing of the Pelamis P2 device with regards to weather windows. It was found that although significant wave height was the primary factor

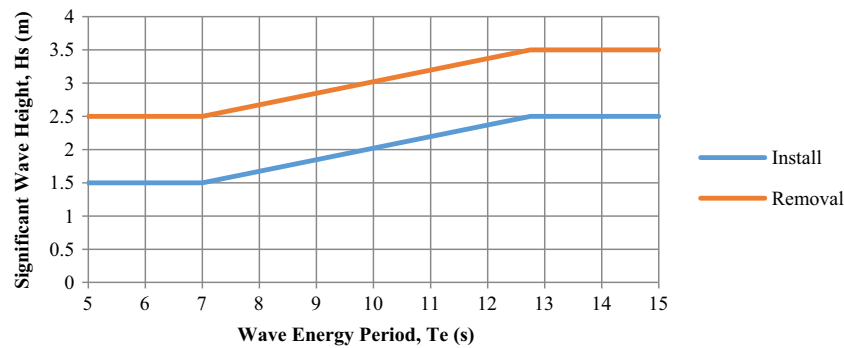

Fig. 4. Operational limits defined during the P2 testing programme and used in the O & M tool for this study (Gray et al., 2015).

in accessibility, operational limits of H_s were also dependent on wave energy period. In addition to H_s and T_e , wind speed has also been included because multicat vessels and tug boats are typically constrained to working in wind speeds of 20 kts or less. Therefore, a wind speed limit of 20 kts has been applied for all marine operations in this study, as well as the H_s and T_e limits shown in Fig. 4.

2.3.4. Yield estimation

In order to estimate the annual yield and energy loss associated with faults and maintenance, this study also includes an assessment of energy generation. A time series of H_s and T_e enables the O & M tool to calculate the estimated power generated by each machine in the wave farm. To achieve this, the weather conditions are matched up with values in a power matrix which has been inferred from the contracted targets that Pelamis Wave Power had during the P2 testing programme (Fig. 5). It should be noted that this power matrix is not intended to be indicative of the true potential of a commercial attenuator WEC. Revenue is then calculated using this energy production multiplied by the unit sell price of electricity. The sell price is assumed to be £305/MWh, in line with the UK's 'Contracts for Difference' model (DECC, 2013)

2.4. Decision making

The O & M tool models a reactive maintenance strategy by using a Monte Carlo analysis at every 6 h time interval. At each time step, a new random number between 0 and 1 is generated for every failure category and compared to the probability of failure for that category (shown in Table A.1, section 9) to determine whether a fault has occurred. The probabilities shown in Table A.1 are adjusted to account for the 6 h resolution using Eq. (1).

$$P_{fail \text{ in } 6hrs} = 1 - (P_{not \text{ fail in year}})^{1/(365 \times 4)} \quad (1)$$

where 365×4 is the total number of 6 h time steps in a year. The decision making process of when to remove and repair a device is represented graphically in Fig. 6. If a device suffers either one major fault or two intermediate ones, then it is retrieved for repair as soon as weather permits. If the device has exceeded the maximum allowable time between two scheduled maintenance events then it is also retrieved. If none of these conditions are met, then the tool runs through a cost-benefit analysis (CBA) to decide whether or not to send a vessel to remove that machine from site (provided the weather window is open). Groups of an increasing number of machines are assessed in turn to enable multiple devices to be removed in the same window if logistics allow. This analysis weighs up the cost of retrieving and repairing the device/s against leaving it/them to operate at a

reduced power output. This becomes quantifiable due to the proactive maintenance strategy of undertaking a routine inspection on each device every summer. Estimates for potential revenue and time spent waiting for a weather window in a given month are provided as an input to enable the cost-benefit calculations to take place.

The results are presented for each machine, for every year of operation, as well as average values given for the entire array. Outputs such as labour costs, vessel fees, availability, total OPEX and revenue are generated. The sixteen failure categories are assigned portions of the OPEX costs based on the downtime due to the associated faults.

2.5. Sensitivity analysis

There is a degree of variability between different model simulations with the same inputs due to the Monte Carlo nature of the O & M tool. To ensure repeatability of results, the seed values of the random numbers for the Monte Carlo analysis could be fixed, thereby simulating the same failures at the same time steps throughout the lifetime of the array. However, this method does not capture the uncertainties which would occur in a real wave energy array. Therefore, for each new inputs scenario presented in this study, the O & M model was run ten times to obtain the mean values. For each series of sensitivity analyses, a base case was simulated with all fault categories set at the original failure rates (see Table A.1, section 9). Martin et al. (2016) undertook a sensitivity analysis on offshore wind farms using the O & M model developed by Douard et al. (2012) and state that an uncertainty envelope of at least 20% should be applied. Therefore, for each subsequent analysis, the failure rate of one fault category was either decreased or increased by a factor of 10 in order to provide clear differences between the results. The failure rate information in the model is provided as a probability of failure per year. Therefore, increasing the rate by a factor of 10 requires the use of Eq. (2).

$$P_{fail: increased} = 1 - (P_{not fail: original})^{0.1} \quad (2)$$

When a failure rate is decreased by a factor of 10, a modified version of Eq. (2) is used, with 10 as the exponent. To assess the true statistical mean of the ten simulations for each analysis, 95% confidence intervals have been applied to the results using the z-value of 1.96, as shown in Eq. (3).

$$x = 1.96 * (\sigma / (n^{0.5})) \quad (3)$$

where x = mean, σ = standard deviation and n = number of simulations.

3. Case study

3.1. O & M tool base case

In order to carry out a sensitivity analysis on the failure rate inputs to the O & M tool, it is vital that a base case is established. This study will model a wave farm containing ten Pelamis P2 devices, operating for a lifespan of twenty years. As previously stated, two multipurpose workboats were required for the installation of a P2 device during the testing programme. However, this is an area where additional experience would yield improved operational procedures in future commercial wave farms. Therefore, the O & M tool assumes that only one multipurpose workboat is required for both installation and removal operations. One workboat is available for the wave farm and is paid for on a 'hire when required' basis. The probability of the boat being available at any given time has been set at 0.9. This accounts for factors such as the vessel being used by the contractor for another job, or undergoing its own maintenance. A mobilisation fee is incurred when the boat is first hired for a period. The vessel stays on hire until all ten devices are back operating in the wave farm. These vessel costs, detailed in Table 1, were the typical market rates during the P2 testing

Table 1:
Cost assumptions in O & M tool.

Vessel Costs		Quayside costs		Labour costs		
Item	Costs (£)	Item	Costs (£)	Technician	Number	Total annual salary (£k)
Mobilisation fee	5000	Base rate (shed rent, insurance etc.)	100 per day	O & M base manager	1	45
Day hire rate	4000	Layage	50 per day	Moorings	2	60
Fuel (per operation)	1000			Hydraulic	3	90
				Structural	3	90
				Electrical	2	60
				Apprentice	1	10
				Contractor fee = £200/day		
				Overheads multiplier = 1.3		

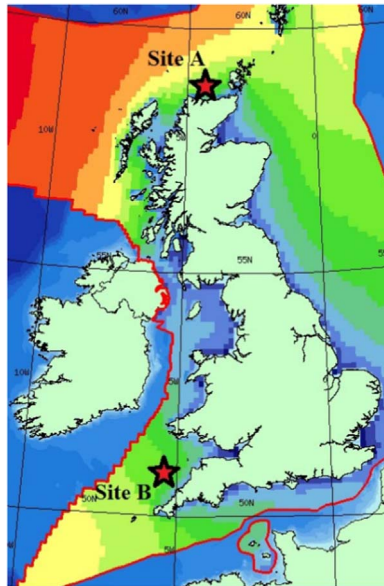

Fig. 7. Annual UK wave resource map (ABP Marine Environmental Research Ltd, 2016) showing approximate locations of the two sites analysed in this study.

programme (2008–2014). The day rate vessel fees are not adjusted for inflation over time in this study. A fuel cost for each operation is also added and is dependent on the distance from the quayside to the wave farm site (discussed in Section 3.2). Quayside fees similar to those incurred by Pelamis Wave Power when testing at EMEC are applied. This includes a daily base rate to cover items such as shed rent and insurance, plus an additional fee for each machine that is at the quayside to cover layage costs. An assumption has been made that marine operations could be carried out at night, as Gray and Johanning (2016) suggested that this arrangement would be beneficial for the profitability of the wave farm. It is also assumed that the quayside could be arranged in such a manner that all ten machines could be stored simultaneously if necessary, and that there are no logistical constraints surrounding which machine can be accessed by the vessel at either the base or the farm.

In addition to the fault categories detailed in Table A.1, there are two scheduled maintenance events built into the O & M model (detailed in Table A.2, section 9). A routine service is scheduled to be carried out once every summer, when accessibility is high and lost revenue is minimised. This event includes tasks such as checking bolt tensions and torque, non-destructive testing (NDT) on welded joints, checking oil cleanliness, removing biofouling and carrying out minor repainting. One specialist technician from each of the hydraulic, structural and electrical departments, as well as one other team member, are required for this event. A specialist moorings technician is not required as no servicing is scheduled to be undertaken on the moorings. The second scheduled maintenance event is a refit of the major components in each

P2 device, to be carried out in the summer of year ten (the half-life of the wave farm). This event was identified as necessary during the design phase of the P2 device because the manufacturers of certain components specified a design life of 10 years. This particularly affected rubber components such as the bellows seals. Therefore, these components would need to be replaced after 10 years in order for the wave farm to achieve its 20 year design lifetime. The half-life refit event also involves tasks such as changing all hydraulic oil, structural surveying, corrosion analysis and a complete repainting of each WEC.

Another input to the O & M tool is the labour details at the operations base. As shown in Table 1, this study assumes a total of twelve personnel permanently employed at the base. A multiplier of 1.3 is applied to account for overheads such as travel expenses and laptops. The O & M tool can constrain repairs and maintenance tasks depending on which technicians are available at any given time. However, for this study, it has been assumed that contractors can be hired on a short term basis at a rate of £200 per day to ensure maintenance is not delayed by a lack of technicians. A study by Gray and Johanning (2016) has shown that this has a significant impact on the operability of the array and therefore could be a realistic scenario once wave energy becomes a commercial industry.

3.2. Site characterisation

This study will look at two specific wave energy sites (see Fig. 7) using the weather simulation model developed for the O & M tool by Gray et al. (2015). Site A is located off the North coast of Scotland and represents Farr Point; a site previously being developed by Pelamis Wave Power as a potential wave array. Site B is found off the North coast of Cornwall and represents Wave Hub; a test facility for offshore renewable energy technologies (Wave Hub Limited, 2015). These sites have been chosen for their significance to the development of the wave energy sector.

3.2.1. Tow times and marine operations

Port selection is required for both sites in order to define the number of P2 installations and/or removals that can be carried out in a 12 h weather window. As shown in Fig. 8, the O & M base for site A would have most likely been located in the natural shelter of Loch Eribol, approximately 30 km from the wave energy array.

Site B is representative of the Wave Hub commercial scale test site off the North coast of Cornwall. A study by Walker et al. (2013) investigated ports in this area suitable for mobilisation of a WEC. Fig. 9 shows the locations of three of the ports considered suitable for access to the Wave Hub site. Hayle port has been assumed as the O & M base for a wave farm located at site B for this study.

Table 2 summarises the key timings to consider when defining the length of a weather window required for the installation or removal of a Pelamis P2 WEC. From this information, it is clear that an installation operation at either site would need a weather window of at least 6 h in length. Therefore, as the resolution of the O & M model used in this

Fig. 8. Map (Google.co.uk) showing distance between Loch Eribol O & M base and site A.

Fig. 9. Map of Cornwall showing three ports suitable for access to Wave Hub (Walker et al., 2013).

study is 6 h, a weather window of 12 h has been selected. However, vessel logistics can be applied to the O & M model to account for the fact that a retrieval operation would take significant less time than an install. As a result, the O & M model used in this study assumes that, in a 12 h window, the vessel can do one of:

- remove a maximum of two P2 devices and bring them both to the quayside
- install one P2 device at the farm
- install one P2 device at the farm, then remove another one and bring it to harbour

3.2.2. Weather conditions

The hindcast data for Site A (Farr Point) is for an 18 year period from 1992 to 2010. It contains all three parameters required to define a weather window for the P2 device (Hs, Te and wind speed). Wave Energy Scotland have provided this dataset for the purposes of this

Table 2:

Breakdown of timings to calculate weather window length.

Description	Notes	Time
Tow time (5kts vessel speed)	30 km to site A 25 km to site B	3hrs 20 mins for site A 2hrs 50 mins for site B
Vessel travel time (15kts assumed vessel speed)	30 km to site A 25 km to site B	1hr 10 mins for site A 1hr for site B
Installation time once at site	Conservative estimate from Yemm et al. (2012)	1hr
Pre-ops required for installation	Yemm et al. (2012)	1.5hrs
Total time required for installation		7hrs 0 min for site A 6hrs 20 min for site B
Retrieval time once at site	Conservative estimate from Yemm et al. (2012)	15 mins
Vessel pre-ops required for retrieval	Yemm et al. (2012)	1hr
Total time required for retrieval		4hrs 45 min for site A 4hrs 5 min for site B

study.

For site B, a 23 year hindcast dataset (1989–2011) for the Cornish coast has been provided by the University of Exeter, as part of the PRIMaRE project (PRIMaRE, 2015). This has been validated against buoy measurements by van Nieuwkoop et al. (2013). However, it is only possible to obtain values for significant wave height and wave energy period from this dataset. In order to match wind speeds to the Hs-Te combinations, data from the Channel Coastal Observatory (CCO) at Perranporth was used (see Fig. 10). This information is readily available from their website (Channel Coastal Observatory, 2015). Real-time data was chosen for the period 12/3/2014 to 10/11/2015 with values obtained for Hs, Te and wind speed in half hourly intervals. After applying the same resolution found in the weather simulation model to these values, it was possible to calculate a probability for every wind speed matching each combination of Hs and Te. This allowed the completion of the 23 year hindcast dataset with the addition of appropriate wind speeds using a Markov-based approach, similar to the method used in the weather simulation model itself (Gray et al., 2015). It should be noted that this method is limited by the fact that extreme waves (i.e. 1 in 100 year storms) will not be accounted for, unless such waves occur in the hindcast dataset. However, the method was deemed suitable for this study as the focus is on the comparison of different simulations.

A comparison between the hindcast data for the two sites in terms of the annual mean values of each of the three parameters can be seen in Figs. 11–13. These graphs show that, overall, the significant wave height and wave energy period are lower at site B than at site A. Conversely, the wind speed is lower on average at site A than at site B.

As stated in Section 2.1, significant wave height and wave energy period are placed into 'bins' with the resolutions 0.5 m and 2 s respectively. As a result, the hindcast data used for input to the Markov-based weather model can be represented graphically by

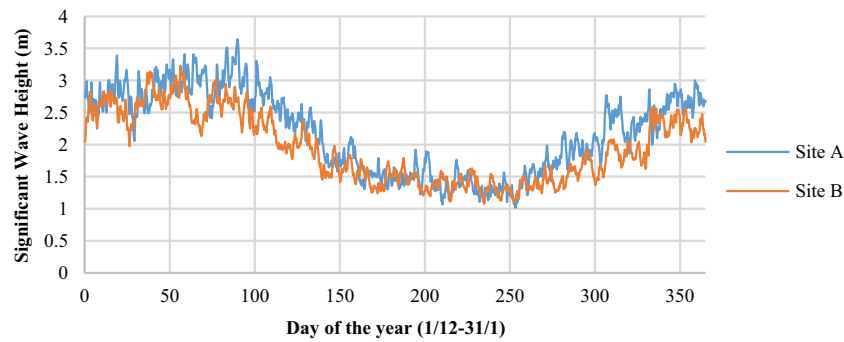

Fig. 11. Mean significant wave height (by day in year) for the two sites.

occurrence tables (see Figs. 14 and 15). It can be seen that site A has a much higher proportion of occurrences in areas of high power capture (when matched to the power matrix, Fig. 5), such as in the 9 s Te, > 1.25 m Hs region.

The O & M tool has the ability to use different 20 year time series' during the sensitivity analysis. However, this would alter the base case for each simulation and therefore only one time series has been used for each site. The cost-benefit analysis part of the O & M tool requires estimates for wait times (i.e. the number of days to wait for a weather window in any given month) and power output. These are obtained by generating a 100 year time series for each site. Therefore, the 20 year time series used for each site in the study was selected based on its similarity to the respective 100 year time series providing estimates to the cost-benefit analysis. The selection process was undertaken by assessing a database of 50 time series' using the criteria of mean annual power, percentage of open weather windows, mean annual wait times, and mean monthly wait times.

Cumulative probability distribution graphs can be plotted to provide further characterisation of the two sites (Figs. 16–19). These graphs have been created by analysing the Markov-generated 100 year time series for each site. Firstly, the persistence of non-accessible weather conditions at each 6 h interval is calculated. The number of occurrences of each persistence time in every month of the year is then recorded, along with the total number of 6 h intervals in that month. This enables the probability of the non-accessible weather conditions not exceeding each cumulative period of time, up to a maximum of 30 days, to be calculated.

4. Results and discussion

4.1. Site characteristics

The site characteristics charts (Figs. 11–13) show that site A has a greater significant wave height and greater wave energy period on average than site B. The implication from this is that site A will have a higher yield in terms of power output of a wave energy farm. However, this may result in weather conditions suitable for marine operations

being more abundant at site B. This effect may be balanced by the wind speed at site A being lower on average than at site B. Figs. 16–19 show the cumulative probability distribution functions of the weather constraints for installation and removal of a P2 device for each season of the year, providing a graphical comparison of wait times for the two sites. This information can be quantified by calculating the average number of days required to wait for a weather window of a certain length in each month (see Fig. 20). A year in the O & M model starts in December, as this makes it easier to assess differences between meteorological seasons.

The cumulative probability distribution functions shown in Figs. 16–19 match up closely for sites A and B. This implies that the time spent waiting for a 12 h weather window would be approximately equal for the two sites. However, from Fig. 20 it can be seen that the estimated average number of 6 h intervals to wait for an open weather window is higher for site A in every month of the year except June. On average, a vessel would need to wait 1.48 days for weather conditions suitable for a 12 h WEC installation in any given month when the wave farm is located at site A, compared to 1.23 days for site B. This information implies that there may be a slightly higher OPEX cost at site A due to the vessel being kept on hire after its first marine operation if another device is to be installed. This difference between the two sites is demonstrated by the base case results from the O & M tool (see Table A.3, section 9). The average OPEX at site A was calculated to be £1.12 m compared to £1.09 m for site B, equating to a 2.6% increase.

4.2. Power estimation and base case results

The Pelamis P2 power matrix (Fig. 5) is matched with the occurrence tables for the two sites (Figs. 14 and 15) to provide the O & M model with estimates of power generation, thereby enabling the cost-benefit calculations to take place. Fig. 21 represents these inputs graphically by comparing the average estimated power generated across a 6 h period for the two sites in each season of the year, as well as providing the average values for the full dataset. This estimation comes from the 100 year dataset used to provide inputs to the cost-

Fig. 14. Occurrence table for site A.

benefit analysis part of the O&M tool, and assumes wave farm availability to be 100%.

Fig. 21 shows that a wave farm located at site A is estimated to generate more power than at site B. The estimated 6 hourly average power output for a single P2 device at Site A is 122.3 kW, compared to 111.2 kW at Site B.

The implication that a Pelamis P2 wave farm located at site A would generate a higher revenue is confirmed by the results of the O&M tool, where the base case annual revenue at site B is £2.57 m compared to £2.85 m at site A (see Table A.3, section 9). This equates to a 9.8% decrease in revenue if the wave farm was located at site B rather than at site A. The base case results also show that there is a negligible 1% difference between the two sites in availability. This is most likely due to the slightly different inputs in terms of estimated wait times and potential revenue, thereby affecting the cost-benefit calculations within the model.

Using the base case results it is also possible to compare the two sites in terms of Levelised Cost of Energy (LCOE). Eq. (4) has been used for these calculations.

$$LCOE = \frac{CAPEX + \sum_{t=1}^n \frac{OPEX_t}{(1+r)^t}}{\sum_{t=1}^n \frac{AEP_t}{(1+r)^t}} \quad (4)$$

where;

LCOE – Levelised Cost of Energy

CAPEX – Capital expenditures

OPEX_t – Operational expenditures (at year t)

AEP_t – Annual electricity production (at year t)

r – Discount rate

n – Lifetime of the system

t – year from start of project

The base case results from the O&M model are used for the OPEX and AEP input parameters in this calculation. The annual revenue is divided by the assumed unit sell price of electricity (£305/MWh) to give an estimate of AEP. Applying an assumed transmission efficiency of 98% leads to the AEP being calculated as 9.15 GWh for site A and 8.26 GWh for site B. A discount rate of 10% has been selected. The total CAPEX of the 10 machine wave farm of £86 m, not including decommissioning fees, has been calculated using the assumptions seen in Table 3.

Using these input parameters, the LCOE is calculated to be £1245/MWh for site A and £1376/MWh for site B. This shows that the greater OPEX incurred by a wave farm located at site A is outweighed by the higher revenue generated. It should be noted that these calculated LCOE values are in no way indicative of the commercial potential of wave energy devices. Offshore wind turbines can be installed at a CAPEX of around £1 m per MW, and achieve capacity factors of up to 40% of rated power. In comparison, the CAPEX assumptions made for

the P2 device have come from pre-commercial devices, and are therefore significantly higher (at approximately £8 m per MW) than would be expected for commercially manufactured WECs. The £20 million allocated to O&M base development is also extremely conservative. In addition, the power matrix input to the O&M model has been inferred from the contracted targets that Pelamis Wave Power had during the P2 testing programme. A commercial WEC would achieve a far greater AEP than has been used for these LCOE calculations. Therefore, the LCOE values presented here are only used for comparison between the two sites, and should not be taken out of this context.

It is reasonable to assume that the estimates of annual energy

production made here could be doubled (i.e. 18.31 GWh for site A and 16.52 GWh for site B) and manufacturing costs could be halved (i.e. £3 m instead of £6 m) once pre-commercial wave energy converters have been developed further. If the O&M base development is allocated £5 m rather than £20 m and the cost of the subsea station is brought down to £0.5 m, then the new estimates for LCOE equate to £324/MWh for site A and £357/MWh for site B. This is similar to other estimates of wave energy LCOE (World Energy Council, 2013), however, it is clearly an area for further research.

The O&M model simulations carried out in this study assume that all maintenance tasks would be undertaken at the ports described in

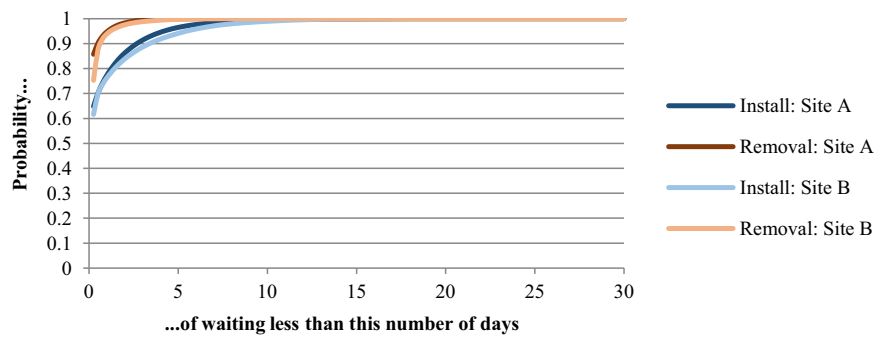

Fig. 18. Cumulative Distribution Functions of installation and removal accessibility during summer (June, July and August) for the two sites used in this study.

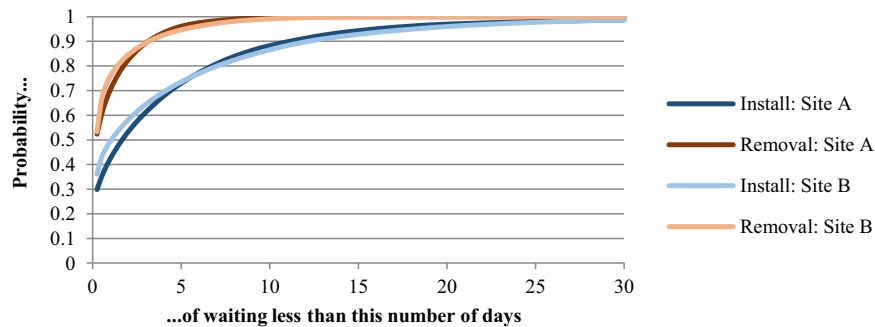

Fig. 19. Cumulative Distribution Functions of installation and removal accessibility during autumn (September, October and November) for the two sites used in this study.

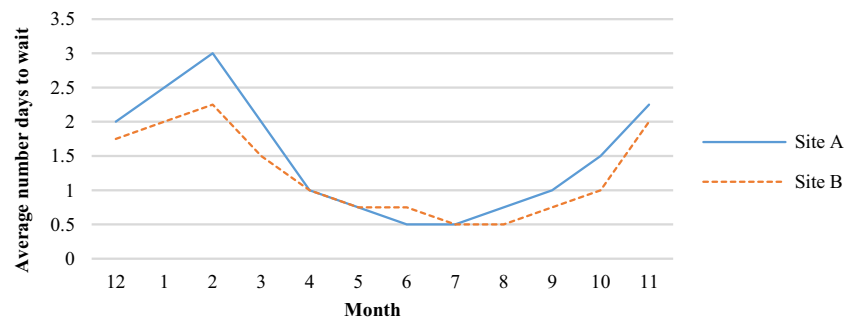

Fig. 20. Comparison of the two sites in terms of the average number of days to wait for a 12 h weather window suitable for installation of a P2 device in each month.

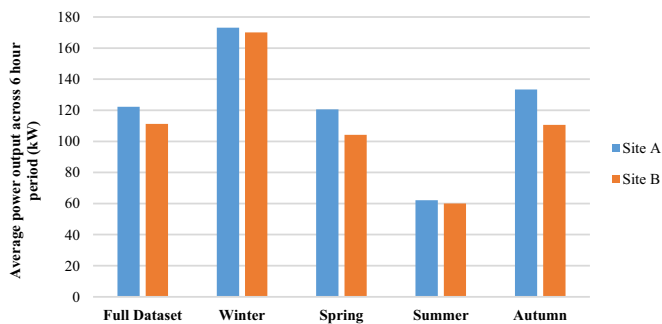

Fig. 21. Comparison of the two sites in terms of average power output (at 100% availability) across a 6 h period.

Section 3.2.1. However, operators of wave energy arrays would have to consider each maintenance task independently. It is likely that more complex tasks would require specialist equipment, such as a dry dock, meaning that the forward O & M base would need careful planning and significant investment. If such upgrades were impossible due to space or logistical restrictions, WECs would need to be taken to larger ports for some maintenance tasks. For site A, this may involve taking the device to Lyness in the Orkney Islands (see Fig. 8), or Penzance if the

farm was at site B (see Fig. 9). Transit times to and from Penzance would also suffer from having to travel around the Cornish headland where tidal conditions would play a part in determining weather windows. Both journeys would require a much greater tow time, resulting in longer waits for a suitable weather window and decreased vessel availability for other WECs at the farm. This would have significant knock-on effects on profitability of the wave energy farm. The assumed O & M base location for site B has also not taken into account that access to Hayle harbour is tidal dependent. This would mean that a vessel towing a WEC into the O & M base would have to wait outside the harbour until the tide allows entry, thereby extending the time to carry out the marine operation.

A more in-depth analysis of weather window lengths and constraints would be required to assess the true impact of using different ports for the O & M activities of the Pelamis wave farm. However, a preliminary analysis provides an indication of the impact of extending the required length of weather window using the same weather constraints. If a 24 h weather window is specified and the same number of marine operations discussed in Section 3.2.1 is used, then the estimated average number of days to wait for a weather window increases significantly from 1.48 and 1.23 up to 4.77 and 4.60 for sites A and B respectively (see Fig. 22).

In addition, the base case results for site B show a significant drop in both availability (4% down) and revenue (3.5% down) when the

Table 3:
Breakdown of CAPEX assumptions.

Item	CAPEX per unit	Notes	Total CAPEX for farm
WEC manufacturing cost	£6 m per WEC	Based on pre-commercial P2 WEC costs	£60 m
WEC insurance	£120k per WEC	2% of device CAPEX	£1.2 m
O & M base development	£20 m	Quayside, shed, office space	£20 m
Licencing and surveys	£0.8 m	Farr Point experience	£0.8 m

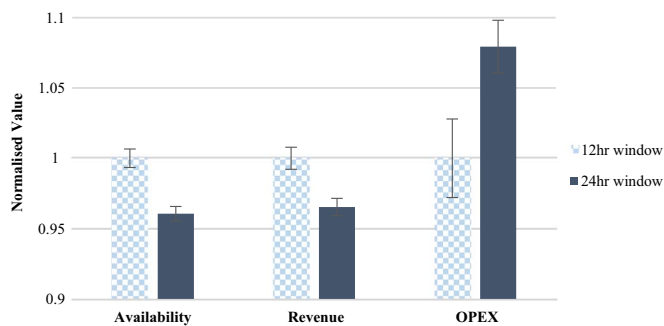

Fig. 23. Effects of an increased length of weather window for site B, normalised against the 12hr base case. 95% confidence intervals applied.

required length of weather window is specified as 24 h rather than 12 h (Fig. 23). This is matched by an OPEX increase of 8%. The applied 95% confidence intervals confirm that the two sets of results are statistically different.

4.3. Failure rate sensitivity

Table A.3 (section 9) contains the numerical results of the sensitivity analysis described in Section 2.3 and Table A.4 provides the percentage changes from the base case.

4.3.1. Minor primary hydraulic faults

From the results of the sensitivity analysis, it can be seen that the biggest drop in profitability of the wave farm occurs when the failure rate for fault category 13 ('minor primary hydraulic') is increased by a factor of 10. The percentage changes from the base case are represented graphically for the two sites in Fig. 24.

Availability decreases from the base case by approximately 22.2% for each of the two sites, whilst revenue decreases by 27.4% and 27.8% for sites A and B respectively. Operational expenditure also increases significantly in this case by 57.7% and 61.5% for sites A and B respectively. As shown in Table A.1 (section 9), the base failure rate for category 13 is a probability of failure per year (P_{fail}) of 0.9375. Increasing this rate by a factor of 10 leads to a probability of failure of 0.9938 per year. Therefore, a minor primary hydraulic failure is almost guaranteed to occur at least once per year on each machine in this

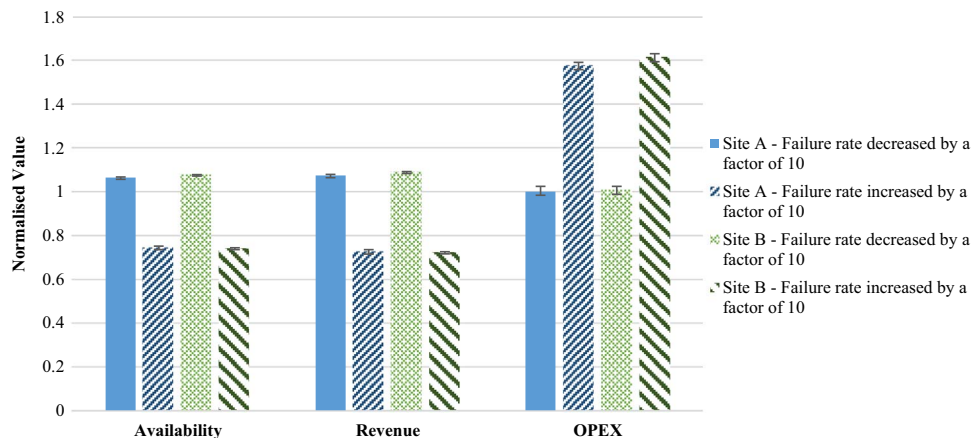

Fig. 24. Sensitivity analysis results for 'Minor primary hydraulic' faults, normalised against the base case.

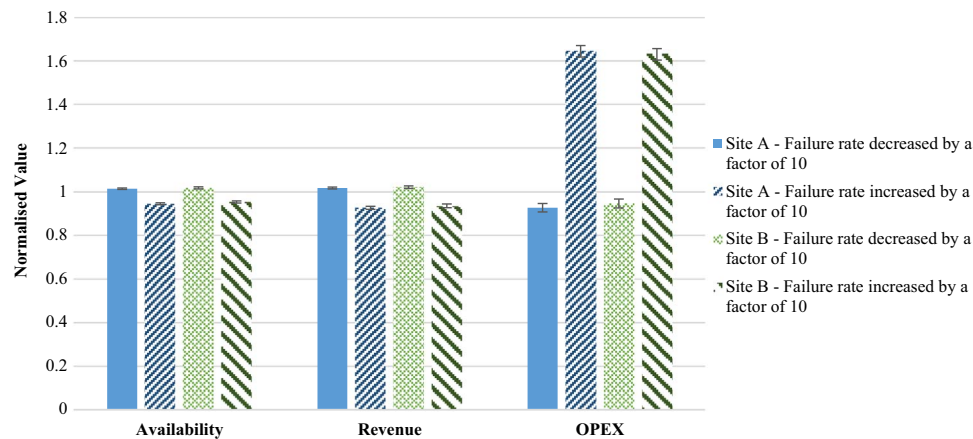

Fig. 25. Sensitivity analysis results for 'Half circuit failure', normalised against the base case.

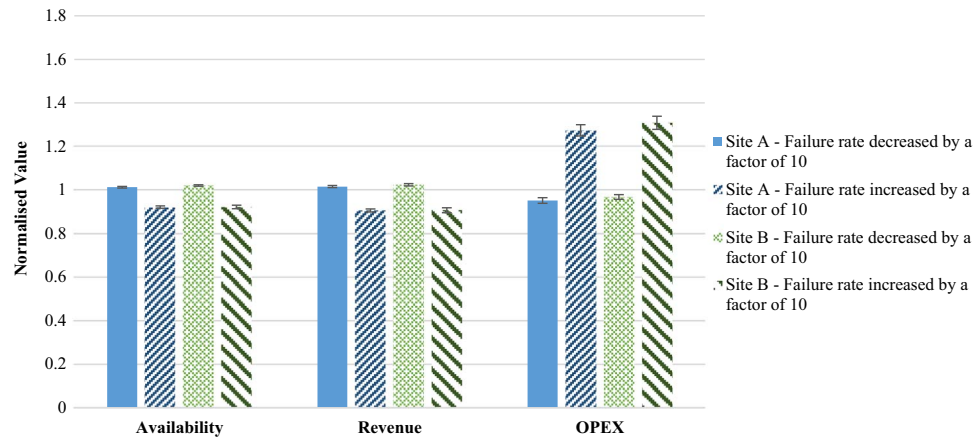

Fig. 26. Sensitivity analysis results for 'Control system faults', normalised against the base case.

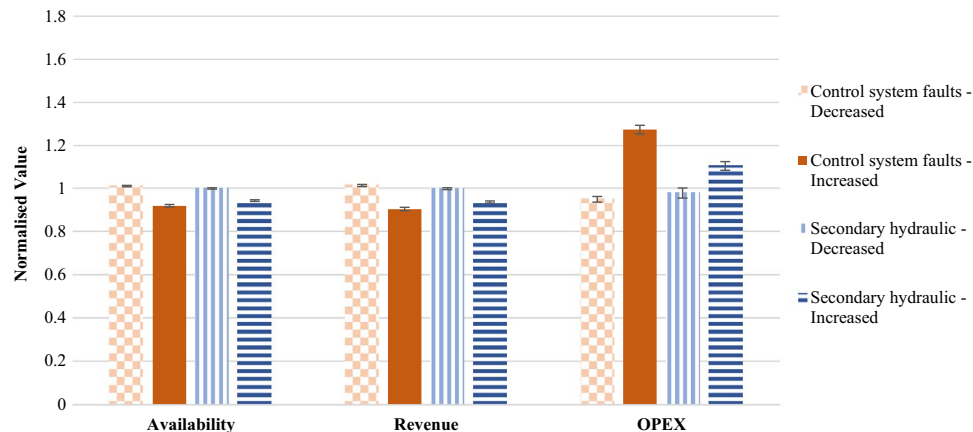

Fig. 27. Comparison of sensitivity analysis results at site A for 'Control system faults' and 'Secondary hydraulic' failures, normalised against the base case.

scenario. On the other hand, the values for associated parameters such as power loss, time off site and repair costs are minimal when compared to other fault categories. However, the results from the sensitivity analysis show that the increased failure rate of minor primary hydraulic faults has a significant impact on operability of the wave farm. This indicates that an increase in the number of minor primary hydraulic faults leads the cost-benefit analysis (CBA) part of the O & M tool to set affected devices for retrieval more than in the base case, regardless of the low-impact associated parameters.

Conversely, when the failure rate for category 13 is decreased by a factor of 10, the results show the largest increases in availability and revenue. With fewer minor primary hydraulic faults occurring in the

farm, the cumulative impact of power loss is reduced when compared to the base case. However, this scenario does not lead to an equally significant decrease in OPEX. An explanation for this could be that the reduced number of minor primary hydraulic faults does not have enough of an impact on the cost-benefit calculations to lead to a decrease in either the average number of marine operations or the time a machine spends off site over the lifetime of the farm.

It is possible to look into the fault category at a component level by investigating the P2 FMEA spreadsheet. From this, it can be seen that the component with the biggest influence on the minor primary hydraulic fault category is the hydraulic valves within the ram manifolds. There are 8 such valves within a single ram manifold, with a total

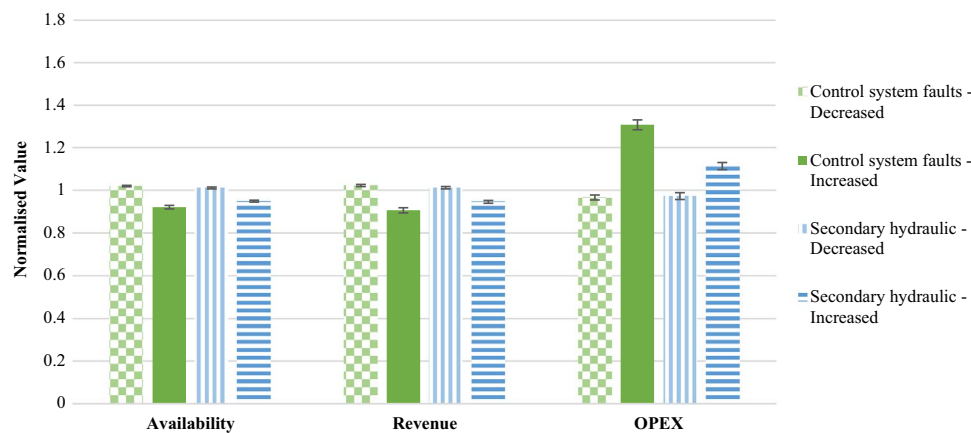

Fig. 28. Comparison of sensitivity analysis results at site B for 'Control system faults' and 'Secondary hydraulic' failures, normalised against the base case.

of 16 manifolds in a Pelamis P2 device. Each of these 128 hydraulic valves has a manufacturer's target Mean Time Between Failure (MTBF) of 100 years. This equates to a total probability of failure of 0.7313 per year, making up the majority of the 0.9375 base failure rate for the minor primary hydraulic fault category. With the results showing that an increase in the number of failures in the minor primary hydraulic fault category could have a significant impact on profitability of the wave farm, it is clear that developers of WECs should work closely with manufacturers to design components specifically for the marine environment, and carry out testing accordingly for more realistic failure rate estimates. Further analysis could investigate the assumed value for power loss due to this failure, as 5% could be deemed too conservative.

4.3.2. Half circuit failure

The biggest increase in OPEX occurs when the failure rate of category 7 ('half circuit failure') is increased by a factor of 10. This is a 64.5% increase for site A and 63.1% for site B, as shown in Fig. 25. There are also decreases in availability and revenue in the region of 4–5% and 6–8% respectively for both sites. There are also minor increases in availability and revenue, and a slight decrease in OPEX, when the failure rate for the half circuit failure category is decreased by a factor of 10.

A Pelamis P2 device was made up of four articulating joints called modules, each housing a hydraulic power take off unit. A half circuit failure is defined as any mechanical or hydraulic fault, such as an oil leak or ram manifold crack, which leads to one half of a module becoming incapable of power generation. This category has the second highest base failure rate ($P_{\text{fail}} = 0.36$) due to the sheer number of potential faults that could contribute to a half circuit failure. In the O & M model, this is classed an intermediate failure where the associated power loss, time off site and repair costs are not particularly large when compared to the major faults. Therefore, it can be assumed that the results of the sensitivity analysis for this category come from the high probability of failure in the base case.

This assumption can be confirmed when compared to the results for category 9 ('data communications'). Here, the power loss and repair parameters are similar to the half circuit failure but with a much lower base failure rate ($P_{\text{fail}} = 0.0139$). The sensitivity analysis for data communications faults shows virtually no impact on operability of the wave farm. This information highlights that in subsystems where many individual faults lead to the same overall failure, those components must be over engineered and thoroughly tested to ensure minimal impact over the lifetime of the wave farm.

4.3.3. Control system faults

The results of the sensitivity analysis are also quite significant for fault category 11 ('control system'), as shown in Fig. 26. When the

control system base failure rate ($P_{\text{fail}} = 0.2604$) is increased by a factor of 10, availability and revenue drop by approximately 7% and 9.5% respectively for both sites. There is some variation between the two sites in terms of the increase in OPEX; 27.4% for site A and 30.8% for site B, although the 95% confidence intervals overlap, implying that the two results are statistically similar. A control system failure is classed as a minor fault and therefore most likely requires other faults to have occurred before the CBA deems it beneficial to repair the affected P2 machine. Again, minor impacts are seen when the base failure rate is decreased by a factor of 10.

Similar to category 7, a control systems failure can arise from several sources such as the pressure sensors in a ram manifold. This cumulative effect leads to the control systems failure having the third largest base failure rate of all 16 fault categories. Obtaining the failure rate for this category is made difficult due to different specifications of pressure sensor having very different failure rates, and also because pressure sensor failure rates are highly dependent on the operating environment. When comparing categories 7 (half circuit failure) and 11 (control systems), it can be seen that they have the exact same values for power loss (0.2), time to fix (2 days) and repair costs (£3000 in total). The three differences that may contribute to the variation in the sensitivity analysis results are the base failure rate ($P_{\text{fail}} = 0.36$ for half circuit failure versus $P_{\text{fail}} = 0.2604$ for control systems failure), classification (intermediate versus minor) and labour requirements (two technicians versus one). Although a previous study has shown labour logistics to have a significant effect on the operability of the wave farm (Gray and Johanning, 2016), the simulations in this paper do not delay repairs due to a lack of technicians. The much larger increase in OPEX when the base failure rate for category 7 is increased by a factor of 10 compared to the same scenario for category 11 (63–65% versus 27–31%) must be attributed to the greater base failure rate. However, this does not explain the variation in availability and revenue. With the half circuit failure having the greater base failure rate, it was expected that the scenario of increasing it by a factor of 10 would lead to a greater decrease in availability and revenue than for the control systems category. The reverse has been shown in the results which could perhaps be explained by the different classifications of the two faults. As stated in the methodology (Section 2), if a device suffers either one major fault or two intermediate ones, then it is retrieved for repair as soon as weather permits. Therefore, the fact that a half circuit failure is classed as an intermediate fault could mean that the O & M model sets devices for immediate retrieval more when the base failure rate is increased, thus avoiding the complexities of the CBA.

Another fault category with similar parameters to the control systems one is category 15; secondary hydraulic failure (see Table A.1, section 9). It has the fourth highest base failure rate at $P_{\text{fail}} = 0.2256$, has total repair costs of £3500, takes one technician two days to carry out the repair and is also classed as a minor fault. The biggest

difference between the two categories is the associated power loss; 0.2 for control systems and 0.06 for secondary hydraulic. The results from the sensitivity analysis show that changing the base failure rate of category 15 has less of an impact than category 11 (Figs. 27–28). This indicates that the power loss associated with a control systems failure is a significant factor. Therefore, redundancy needs to be built into WEC subsystems in order to minimise the power loss and improve the profitability of the wave farm.

4.3.4. Faults leading to immediate recovery

Category 2 ('major structural failure – no warning') shows the third largest increase in OPEX when the base failure rate is increased by a factor of 10 (see Table A.4), at 54% and 56.4% for sites A and B respectively. However, the decrease in availability (~1%) and revenue (~1.5%) is negligible in comparison. This difference is due to the classification of category 2 as a major failure. The O & M tool does not enter the cost-benefit analysis calculations when a major failure occurs, instead it sets the affected machine for removal and repair as soon as a weather window is open. This effect can also be seen to a lesser extent in the results for categories 1 ('major mooring') and 3 ('major structural – identified'). Category 2 sees the largest impacts because it has the highest failure rate of the three and requires the longest time off site for repair (see Table A.1, section 9). This decision making process also occurs when power output on a machine drops to zero, which is why similar results are produced for category 10 ('electrical unions & tieback'), even though it is classed as intermediate. The base failure rates for these four categories are already so minimal that similar impacts do not occur when the failure rate is decreased by a factor of 10.

5. Conclusions

This study has seen an Operations and Maintenance (O & M) simulation tool used to address the two issues of site characteristics affecting accessibility and power performance of wave energy arrays, and uncertainty surrounding failure rate estimates. The Monte Carlo-based O & M tool uses failure rate data that has been obtained for the Pelamis P2 device to model the operations and maintenance activities undertaken on a 10 machine wave farm over a lifetime of 20 years. The tool uses the Pelamis approach of using low cost vessels for rapid installation and removal of devices, with repairs taking place offsite at a sheltered quayside. The majority of the inputs to the model, including the failure rate data, have been informed by the P2 testing programme undertaken at the European Marine Energy Centre (EMEC) from 2008 to 2014. One key input is a weather time series containing values for significant wave height, wave period and wind speed. Two sites at opposite ends of the UK have been analysed in this study.

Characteristic analysis of the two sites initially showed that there was very little difference in terms of accessibility. Some variation in power performance was, however, identified when the occurrence tables for the two sites were matched to the power matrix for the Pelamis P2 device. The outputs of the O & M tool confirmed the expected variation in power performance, where a 10% difference in revenue was identified between the two sites, based on device performance in different wave climates. These results suggest that a wave energy converter (WEC) should be designed for the weather conditions at a specific site in order to maximise revenue. Despite the differences between the two sites in terms of revenue and OPEX identified in the base case results, the sites match in terms of the relative trends of fault category sensitivity; demonstrating that a sensitivity analysis does not need to be undertaken for every new site considered. This was to be expected as the failure rates remain constant for each simulation and are not affected by changes in weather conditions. A more comprehensive assessment of the site differences could be achieved by having the failure rate inputs of certain components dependent on weather conditions. Further real sea testing

by WEC developers is required before this level of data becomes available.

The sensitivity analysis on the failure rate inputs to the O & M tool has identified hydraulic valves as the component most sensitive to changes in estimated failure rate in the Pelamis P2 device. Although a simple parts count would show that hydraulic valves are the most abundant component in the WEC, the method of simulating lifetime O & M shows exactly what the impact of these components failing is on overall array performance. To minimise the uncertainty surrounding failure rates of these valves, as well as other components, WEC developers should collaborate with manufacturers to design and test components for the marine environment. In cases where several individual faults can cause the same overall failure within a WEC, the associated components must be over engineered and tested to reduce the impact on operability of a wave farm. In addition, redundancy of components must be built in to WEC subsystems to minimise the power loss associated with faults. It is vital that major failures, such as a structural breach, are considered and planned for in order to deal with such occurrences in a rapid and co-effective manner.

This study has demonstrated how an O & M simulation tool can enable effective budgeting and planning of a wave energy farm. It has highlighted how the tool can assist in strategic decision making such as port location and farm design. In addition, by using an O & M model to undertake a sensitivity analysis, a technology developer will be able to prioritise the design of certain components and subsystems to ensure that the WEC achieves its full potential when deployed in a wave farm.

6. Further work

At present, the failure rate data is given to the O & M tool as constant values throughout the lifetime of the wave energy array. This is a flawed assumption as some components within a WEC would be likely to degrade over time, as well as being affected by changes in weather conditions. It is also true that the failure rates presented in this study are likely to be more representative of 'early failure rates', given that the values have been inferred from the experience gained during the Pelamis P2 testing programme. Future O & M tools should be more realistic in this regards, perhaps by applying a Weibull distribution model to replicate component degradation. This would also pave the way for incorporating a predictive maintenance strategy, whereby WECs are scheduled for inspection when certain components have reached a certain level of risk in terms of potential failure. Increased application of condition monitoring systems in real-sea wave energy testing programmes is vital for this type of failure rate modelling.

In order to obtain realistic outputs, a wave energy O & M simulation tool must be device specific due to the complexity of the inputs and variables involved. There is no such thing as a *realistic* and *generic* O & M tool for WECs because of the lack of convergence on a single device design. Many of the inputs contain a level of uncertainty which can be addressed through further sensitivity analysis. An example is the vessel costs where, for this study, a day rate has been assumed and unaltered for inflation over time. Further work will involve assessing different vessel hire or purchase arrangements to identify the optimal strategy for wave farm logistics. The O & M tool is also a 'living' software tool in that real sea testing will improve the inputs to the model and therefore provide more confidence in the outputs. Further work will involve identifying the development steps required to build the O & M tool around another wave energy device. Such a process will be extremely useful for developers of WEC technology at an early stage of development because the O & M tool outputs can provide feedback into the design of their devices, thus enabling iterative improvements. Once a WEC developer has achieved a level of operational experience with their device, the O & M tool could be used for due diligence and cost estimation, thereby making projects more attractive for commercial investment.

Acknowledgements

The authors' appreciation of the Pelamis engineers who undertook the P2 testing programme and provided the inputs for the O & M tool used in this study is warmly noted. Wave data for site B was provided by the University of Exeter, and the matching wind speed data was obtained from the Channel Coastal Observatory's MET station, in-

stalled by the University of Plymouth. The lead author would also like to thank Wave Energy Scotland, the IDCORE programme and its funding bodies, in particular the ETP (Energy Technology Partnership), for their support. IDCORE is funded by the Energy Technology Partnership and the RCUK Energy Programme; Grant number EP/J500847/1.
