A Detailed description of simulator models used in experiments

A.1 A toy problem with complex posterior

This toy model illustrates that even simple models can have non-trivial posteriors. The model has 5 parameters $\theta = (\theta_1, \ldots, \theta_5)$ sampled from a uniform prior as follows:

$$\theta_i \sim U(-3, 3) \quad \text{for} \quad i = 1, \ldots, 5. \quad (1)$$

Given parameters $\theta$, the data $x$ is generated as follows:

$$m_\theta = (\theta_1, \theta_2) \quad (2)$$

$$s_1 = \theta_3^2 \quad (3)$$

$$s_2 = \theta_4^2 \quad (4)$$

$$\rho = \tanh(\theta_5) \quad (5)$$

$$S_\theta = \begin{pmatrix}
  s_1^2 & \rho s_1 s_2 \\
  \rho s_1 s_2 & s_2^2
\end{pmatrix} \quad (6)$$

$$x_j \sim N(m_\theta, S_\theta) \quad \text{for} \quad j = 1, \ldots, 4 \quad (7)$$

$$x = (x_1, \ldots, x_4). \quad (8)$$

The data $x$ is 8-dimensional. The likelihood is:

$$p(x | \theta) = \prod_{j=1}^4 N(x_j | m_\theta, S_\theta). \quad (9)$$

In our experiments, we took the ground truth parameters to be:

$$\theta^* = (0.7, -2.9, -1, -0.9, 0.6), \quad (10)$$

and simulated the model with parameters $\theta^*$ to get observed data $x_o$.

A.2 M/G/1 queue model

The M/G/1 queue model [8] describes how a server processes a queue of arriving customers. Our experimental setup follows Papamakarios and Murray [6].

There are 3 parameters $\theta = (\theta_1, \theta_2, \theta_3)$ sampled from a uniform prior as follows:

$$\theta_1 \sim U(0, 10) \quad (11)$$

$$\theta_2 - \theta_1 \sim U(0, 10) \quad (12)$$

$$\theta_3 \sim U(0, 1/3). \quad (13)$$

Let $I$ be the total number of customers, $s_i$ be the time the server takes to serve customer $i$, $a_i$ be the time customer $i$ arrived, and $d_i$ be the time customer $i$ departed. Take $a_0 = d_0 = 0$. The M/G/1 queue model is described by:

$$s_i \sim U(\theta_1, \theta_2) \quad (14)$$

$$a_i - a_{i-1} \sim \text{Exp}(\theta_3) \quad (15)$$

$$d_i - d_{i-1} = s_i + \max(0, a_i - d_{i-1}). \quad (16)$$

In our experiments we used $I = 50$. The data $x$ is 5-dimensional, and is obtained by (a) calculating the 0th, 25th, 50th, 75th and 100th quantiles of the set of inter-departure times $\{d_i - d_{i-1}\}_{i=1}^I$, and (b) linearly transforming the quantiles to have approximately zero mean and unit covariance matrix. The parameters of the linear transformation were determined by a pilot run. We took the ground truth parameters to be:

$$\theta^* = (1, 5, 0, 2), \quad (17)$$

and simulated the model with parameters $\theta^*$ to get observed data $x_o$.

A.3 Lotka–Volterra population model

The Lotka–Volterra model [10] is a Markov jump process describing the evolution of a population of predators interacting with a population of prey, and has four parameters $\theta = (\theta_1, \ldots, \theta_4)$. Let $X$ be the number of predators, and $Y$ be the number of prey. According to the model, the following can take place:

- With rate $\exp(\theta_1)XY$ a predator may be born, increasing $X$ by one.
We recorded the two populations every 0.2 time units; each time series features:

- The mean of each time series.
- The log variance of each time series.
- The autocorrelation coefficient of each time series at lags 0.2 and 0.4 time units.
- The cross-correlation coefficient between the two time series.

Each feature was normalized to have approximately zero mean and unit variance based on a pilot run. The ground truth parameters were taken to be:

\[ \theta^* = (\log 0.01, \log 0.5, \log 1, \log 0.01), \]

and the observed data were generated from a simulation of the model at \( \theta^* \). In our experiments we used two priors: (a) a broad prior defined by:

\[ p_{\text{broad}}(\theta) \propto \prod_{i=1}^{4} I(-5 \leq \theta_i \leq 2), \]

and (b) a prior corresponding to the oscillating regime, defined by:

\[ p_{\text{osc}}(\theta) \propto N(\theta | \theta^*, 0.5^2) p_{\text{broad}}(\theta). \]

A.4 Hodgkin–Huxley cortical pyramidal neuron model

In neuroscience, the formalism developed by Hodgkin–Huxley in their classic model of the squid giant axon [4] is used to model many different types of neuron. In our experiments, we used a slightly modified version of a regular-spiking cortical pyramidal cell [7], for which NEURON simulation code is available in ModelDB [1].

The model is formulated as a set of five coupled ordinary differential equations (ODEs) and describes how the electrical potential \( V(t) \) measured across the neuronal cell membrane varies over time as a function of current \( I_c(t) \) injected through an electrode. In essence, the membrane is a capacitor punctuated by conductances formed by multiple types of ion channel through which currents flow. The currents charge and discharge the membrane capacitance, causing the membrane potential to change, as described by the first ODE, the membrane equation:

\[ C_m \frac{dV}{dt} = -I_l - I_{Na} - I_K - I_M - I_e. \]  

Here, \( C_m = 1 \mu F cm^{-2} \) is the specific membrane capacitance, and \( I_l, I_{Na}, I_K \) and \( I_M \) are the ionic currents flowing through 'leak' channels, sodium channels, potassium delayed-rectifier channels and M-type potassium channels respectively. Each ionic current depends on a conductance that corresponds to how many channels are open, and on the difference between the membrane potential and an equilibrium potential. For example, for the leak current:

\[ I_l = g_l (V - E_l), \]

where \( g_l \) is the leak conductance, and \( E_l \) is the leak equilibrium potential. Here the conductance \( g_l \) is constant through time, but for the sodium, potassium and M-type channels, the conductances vary over time, as described by the product of a fixed conductance and time-varying state variables:

\[ I_{Na} = g_{Na} m^3 h (V - E_{Na}) \]
\[ I_K = g_K n^4 (V - E_K) \]
\[ I_M = g_M p (V - E_K). \]

Here, \( g_{Na}, g_K \) and \( g_M \) are the per-channel maximum conductances, \( m, n \) and \( p \) are state variables that range between 0 and 1, and \( E_{Na} \) and \( E_K \) are the sodium and potassium reversal potentials. The state variables evolve according to differential equations of the form first introduced by Hodgkin and Huxley [4]:

\[ \frac{dx}{dt} = \alpha_x(V) (1 - x) - \beta_x(V) x \quad \text{for} \ x \in \{m, h, n\} \]
\[ \frac{dp}{dt} = \frac{p - p_{\infty}(V)}{\tau_p(V)}. \]

where \( \alpha_x(V), \beta_x(V), p_{\infty}(V) \) and \( \tau_p(V) \) are nonlinear functions of the membrane potential. We use the published equations [7] for \( \alpha_m(V), \beta_m(V), \alpha_h(V), \beta_h(V) \) and \( \alpha_i(V) \), which contain a parameter \( V_T \), and the published equations for \( p_{\infty}(V) \) and \( \tau_p(V) \), the latter of
which contains a parameter $\tau_{\text{max}}$. We use a generalized version of $\beta_n(V)$:

$$\beta_n(V) = k_{\beta n1} \exp \left(-\frac{V - V_T - 10}{k_{\beta n2}}\right)$$  \hspace{1cm} (28)

in which $k_{\beta n1}$ and $k_{\beta n2}$ are adjustable parameters (rather than 0.5 ms$^{-1}$ and 40 mV). In order to simulate the model, we use NEURON \cite{1} to solve the ODEs numerically from initial conditions of:

$$m = h = n = p = 0 \quad \text{and} \quad V = -70 \text{mV},$$  \hspace{1cm} (29)

using the “CNexp” method and a time-step of 25 ms. At each time step the injected current $I_e$ is drawn from a normal distribution with mean 0.5 nA and variance $\sigma^2$. The duration of the simulation is 100 ms and the voltage is recorded, which generates a timeseries of 4001 voltage recordings.

Our inference setup follows Lueckmann et al. \cite{5}. There are 12 parameters $\theta = (\theta_1, \ldots, \theta_{12})$ to infer, defined as:

$$\begin{align*}
\theta_1 &= \log(g_k) \\
\theta_2 &= \log(g_{Na}) \\
\theta_3 &= \log(E_K) \\
\theta_4 &= \log(E_{Na}) \\
\theta_5 &= \log(-E_t) \\
\theta_6 &= \log(\sigma) \\
\theta_7 &= \log(-E_K) \\
\theta_8 &= \log(-V_T) \\
\theta_9 &= \log(k_{\beta n1}) \\
\theta_{10} &= \log(k_{\beta n2}) \\
\theta_{11} &= \log(\tau_{\text{max}}) \\
\theta_{12} &= \log(\sigma). 
\end{align*}$$  \hspace{1cm} (30)

The data $x$ is taken to be 18 features of the voltage timeseries $V(t)$, in particular:

- The mean and log standard deviation of $V(t)$.
- The normalized 3rd, 5th and 7th moments of $V(t)$.
- The logs of the normalized 4th, 6th and 8th moments of $V(t)$.
- The autocorrelation coefficients of $V(t)$ at lags $k \times 2.5$ ms for $k = 1, \ldots, 10$.

The features are linearly transformed to have approximately zero mean and unit covariance matrix; the parameters of the transformation are calculated based on a pilot run. The ground truth parameters $\theta^*$ are taken to be:

$$\begin{align*}
\theta_1^* &= \log(10^{-4}) \\
\theta_2^* &= \log(0.2) \\
\theta_3^* &= \log(0.05) \\
\theta_4^* &= \log(7 \times 10^{-5}) \\
\theta_5^* &= \log(70) \\
\theta_6^* &= \log(50) \\
\theta_7^* &= \log(100) \\
\theta_8^* &= \log(60) \\
\theta_9^* &= \log(0.5) \\
\theta_{10}^* &= \log(40) \\
\theta_{11}^* &= \log(1000) \\
\theta_{12}^* &= \log(1). 
\end{align*}$$  \hspace{1cm} (31)

The prior over parameters is:

$$\theta_i \sim \mathcal{U}(\theta_i^* - \log 2, \theta_i^* + \log 1.5) \quad \text{for} \quad i = 1, \ldots, 12.$$  \hspace{1cm} (32)

Finally, the observed data $x_o$ were generated by simulating the model at $\theta^*$.

### B Full experimental results

In this section, we include the full set of experimental results. For each simulator model, we report:

- The approximate posterior computed by SNL.
- The trade-off between accuracy and simulation cost. This is reported for all methods.
- The full results of the simulation-based calibration test, consisting of one histogram per parameter.
- The distance-based convergence diagnostic, i.e. the distance between simulated and observed data vs the number of rounds. This is reported for SNL, SNPE-A and SNPE-B.
- The goodness-of-fit diagnostic, i.e. the Maximum Mean Discrepancy between simulated data and data generated from the likelihood model, for a given parameter value (we use the true parameters $\theta^*$). We report this for SNL, NL and a baseline Gaussian fit.

#### B.1 A toy problem with complex posterior

Figure 1 shows the results. The exact posterior $p(\theta | x_o)$ is plotted in Figure 1a. Even though the prior is uniform and the likelihood is Gaussian, the posterior is complex and non-trivial: it has four symmetric modes due to the two squaring operations in Equations (28) and (29), and vertical cut-offs due to the hard constraints imposed by the prior. We can see that the SNL posterior (Figure 1b) approximates the exact posterior well.

#### B.2 M/G/1 queue model

Figure 2 shows the results. The SNL posterior is shown in Figure 2a. We can see that the posterior is concentrated around the true parameters. Parameter $\theta_1$ is particularly well constrained. From the description of the model in Equations (11)–(13), it directly follows that:

$$\theta_1 \leq \min_i (d_i - d_{i-1}).$$  \hspace{1cm} (33)

The data $x$ is an invertible linear transformation of the quantiles of $(d_i - d_{i-1})_{1:j}$ including the 0th quantile, which is precisely equal to $\min_i (d_i - d_{i-1})$. Hence, the data $x$ imposes a hard constraint on the maximum
The longer tail of the potassium equilibrium potential reflects that concentrations, and increasing voltage of potassium conductances, and increasing \( k_{\beta n2} \) makes the slope of transition less pronounced. The lack of posterior at high \( k_{\beta n1} \) (high threshold) and low \( k_{\beta n2} \) (sharper transition) might cause the neuron not to repolarize quickly enough, and hence be hyperexcitable.

Finally, we note that the posterior computed by SNL is qualitatively consistent with the posterior reported by Lueckmann et al. \[5\] in Figure G.2 of their article.
