ABSTRACT

The usual attention mechanisms used for encoder-decoder models do not constrain the relationship between input and output sequences to be monotonic. To address this we explore windowed attention mechanisms which restrict attention to a block of source hidden states. Rule-based windowing restricts attention to a (typically large) fixed-length window. The performance of such methods is poor if the window size is small. In this paper, we propose a fully-trainable windowed attention and provide a detailed analysis on the factors which affect the performance of such an attention mechanism. Compared to the rule-based window methods, the learned window size is significantly smaller yet the model’s performance is competitive. On the TIMIT corpus this approach has resulted in a 17% (relative) performance improvement over the traditional attention model. Our model also yields comparable accuracies to the joint CTC-attention model on the Wall Street Journal corpus.

Index Terms— end-to-end, speech recognition, attention

1. INTRODUCTION

Attention-based encoder-decoder models have offered impressive performance gains in tasks such as image caption and machine translation [1, 2, 3]. However, for speech recognition, without a large amount of training data, the attention-based encoder-decoder model often does not outperform traditional models [4].

A weakness of this model for speech recognition is that the attention mechanism does not guarantee a monotonic alignment between the input and output sequences, which usually follow a left-to-right order. Since the attention mechanism relies heavily on the content of the hidden representations of the input units, a monotonic alignment is easily corrupted by similar input speech fragments or noise. Furthermore, the attention mechanism considers all input frames when calculating the alignment vector. However, since one output unit usually only corresponds to a small input time span, it is arguably unnecessary to consider the entire input sequence when estimating the alignment.

Several mechanisms have been proposed for location-aware or coverage-aware attention. At a decoding time step, the attention vector at the previous time step or the alignments of all previous output units are exploited to generate the current attention vector [5, 6]. Thereby, the attention mechanism has an awareness of the location or the coverage [7]. However, this approach does not guarantee the best performance [8].

Other methods which add a location constraint to the attention mechanism include a model in which both connectionist temporal classification (CTC) and an attention model share the same encoder – joint CTC-attention [9, 10]. In this case, CTC provides a soft left-to-right constraint. Windowing methods put a hard location constraint on the attention mechanism, restricting attention to a window of inputs [8, 11, 12, 13]. When the method of moving the window is rule-based, it is necessary to set the window size to be large (typically comparable to the utterance length) for accurate results [8, 11, 12, 13]. When the step size is learned, a short fixed-size window can yield good results [14]. There is no analysis on why with a trained step size small window can suffice. Furthermore, the window size is not trainable in these methods.

Inspired by the local attention mechanism [3], this paper proposes a novel fully-trainable windowed attention for speech recognition. Within the window, a Gaussian distribution or a concatenation of two sigmoid functions are used to predict a location score. We also employ a model to predict the step size and window size, consequently make these two window parameters trainable. To generate content scores, we used content-based attention. In the proposed approach the final attention score was the product of the location score and the content score. Compared to rule-based window methods [8, 11, 12, 13], the learned window size in our method is notably smaller. In terms of accuracy, the proposed model outperforms content-based attention on TIMIT and has comparable results to joint CTC-attention on WSJ.

During our experiments, we found a key aspect in predicting the window size is to prevent it from shrinking to zero. We also found that even given a rough segmentation, it is still hard for the content-based attention to generate the best alignment. We observed that the silence parts in an utterance harm the performance of the model significantly. To cope with this issue, we padded the silence part in the beginning of each utterance with some padding characters which led to noticeable performance improvement of the model.
The attention based encoder-decoder model computes the probability \( P(Y|X) \) of an output sequence \( Y = y_1, \ldots, y_n \) conditioned on an input sequence \( X = x_1, \ldots, x_n \). The encoder reads the input sequence \( X \) and use an RNN to map it to a sequence of encoder RNN hidden states \( H = (h_1, \ldots, h_N) \).

At each decoding time step \( i \), the decoder RNN uses the previous output \( y_{i-1} \), the previous decoder RNN hidden state \( q_{i-1} \) and the previous context vector \( c_{i-1} \) to generate the current decoder hidden state \( q_i \). The attention mechanism uses the current decoder hidden state \( q_i \) and the sequence of encoder hidden states \( H \) to compute an alignment vector \( \alpha_i \). Given the alignment vector \( \alpha_i \), as weights, a context vector \( c_i \) is computed as a weighted sum of the source hidden states. Finally, the decoder uses the context vector \( c_i \) and the current decoder hidden state \( q_i \) to estimate the current label distribution \( P(y_i|X, y_{1:i-1}) \). The decoder can be described as follows:

\[
q_i = \text{RNN}(q_{i-1}, y_{i-1}, c_{i-1}) \tag{1}
\]

\[
\alpha_{ij} = \text{Attention}(q_i, h_j) \tag{2}
\]

\[
c_i = \sum_j \alpha_{ij} h_j \tag{3}
\]

\[
y_i \sim \text{LabelDistribution}(c_i, q_i) \tag{4}
\]

The attention mechanism estimates the alignment between the current output \( y_i \) and all the input units. There are several approaches to compute the attention vector. The following equations describe two approaches:

\[
e_{ij} = v^T \tanh(W q_i + V h_j + b) \quad \text{(Content)} \tag{5}
\]

\[
e_{ij} = v^T \tanh(W q_i + V h_j + U f_i + b) \quad \text{(Location)} \tag{6}
\]

\[
f_i = F \ast c_{i-1} \tag{7}
\]

where \( v, W, V, U, F, b \) are trainable parameters. The final attention vector is:

\[
\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_k \exp(e_{ik})} \tag{8}
\]

2. ATTENTION MECHANISMS

2.1. Rule-based windowed attention

A weakness of the attention mechanism for speech recognition is that it is too flexible and does not guarantee the generation of a monotonic alignment, since similar input units or noise can cause misalignment. Furthermore, the above attention mechanisms consider the entire sequence of encoder hidden states, which may not be necessary for speech recognition, since each output label (typically a phoneme or a character) corresponds to a small span of input signal.

Windowed attention mechanisms, in which the attention is constrained to consider a window of the input, are proposed to alleviate these problems. The window moves from left to right along the input time axis, helping to generate a monotonic alignment. In rule-based windowed attention methods [8, 11, 12, 13], the attention vector \( \alpha_i \) can be described as:

\[
\alpha_{ij} = \begin{cases} 
\frac{\exp(e_{ij})}{\sum_{k=m_l}^{m_r} \exp(e_{ik})}, & j \in [m_l - D_l, m_l + D_r] \\
0, & \text{otherwise}
\end{cases} \tag{9}
\]

where \( m_l \) is the centre of the window, and \( D_l \) and \( D_r \) are the size of the left half and right half of the window respectively. The method of moving the window and the window length are pre-defined. The window shift and window length are not trainable.

Such rule-based window methods have been found to require a large window size – often close to the length of the entire utterance – in order to get good performance [8, 13]. However, if the window size is comparable to the utterance length, then it does not particularly help to generate a monotonic alignment nor to reduce the computational effort.

2.2. Fully-trainable windowed attention

To alleviate these problems, we propose a fully-trainable windowed attention (Figure 1). In this model, all the window parameters are trainable and the learned window size is small. The step size \( s_i \) is predicted by an MLP:

\[
s_i = N \cdot \text{sigmoid}(\text{MLP}(q_i)), \tag{10}
\]

where \( N \) is the maximum allowed step size and set as a hyperparameter. The model records the window centre at the previous decoding time step.

Within the window, we use content-based attention to compute the content score \( e_{ij} \). We use a differentiable function to calculate the location score \( l_{ij} \). The differentiable function also

![Fig. 1: The windowed attention mechanism. At decoding time step \( i \), the system uses an MLP to estimate a step size \( s_i \). The centre of the window is moved from \( m_{i-1} \) to \( m_i \). Only the encoder hidden states which are within the window will be exploited to calculate the context vector. The window length can either be set as a hyperparameter or learned.](image-url)
makes the step size and window size trainable. We choose two
differentiable functions, the Gaussian distribution,
\[
I_{ij} = \begin{cases} 
\exp(-\frac{(j-m_i)^2}{2D_l^2}), & j \in [m_i - D_l, m_i] \\
\exp(-\frac{(j-m_i)^2}{2D_r^2}), & j \in (m_i, m_i + D_r] 
\end{cases}
\]
and the concatenation of two sigmoid functions,
\[
I_{ij} = \begin{cases} 
s\sigma(k \cdot (j - m_i) + b), & j \in [m_i - D_l, m_i] \\
s\sigma(k \cdot (m_i - j) + b), & j \in (m_i, m_i + D_r] 
\end{cases}
\]
where \(D_l\) and \(D_r\) denote the length of the left and the right
half windows respectively while \(k\) and \(b\) are hyperparameters.
The final weight is defined as:
\[
\alpha_{ij} = \frac{\exp(e_{ij}) \cdot I_{ij}}{\sum_{k=m_l}^{m_r+D_r} \exp(e_{ik}) \cdot I_{ik}}.
\]
The Gaussian distribution makes the final weight tend to be
large near the centre of the window. Thus, it provides a strong
location constraint. The sigmoid functions, when the hyperparameter \(b\) is set large, has large values within the
window. Thus, they nearly only provide the indices of the most
related encoder hidden states and the content-based attention
almost solely determines the final weight.

When the half window sizes \(D_l\) and \(D_r\) are equal, the
location score is symmetrically distributed within the window.
When they are different, the location score makes the model
tend to further rely on the past or the future context. The half
window sizes can either be set as hyperparameters or learned
by one MLP so the window is symmetric or learned by two
MLPs so the window may be asymmetric. The window size
MLP is defined as:
\[
D_i = D \cdot \text{sigmoid}(\text{MLP}(q_i))
\]
where \(D\) is the maximum allowed half window size.

3. EXPERIMENTS

We performed two sets of experiments: phoneme recognition on
TIMIT [15] and character recognition on WSJ1 [16] and
subsets of WSJ1. The TIMIT dataset is split into training,
development, and test sets following the Kaldi s5 recipe [17].
We use 80 mel-scale filter-bank features with energy as input
features. The outputs are 39 phonemes with start/end sentence
(sos/eos) and space tokens.

For the WSJ dataset, we use train_si284 as the training set,
dev93 as the development set and eval92 as the test set.
The input features are 40 mel-scale filter-bank features with delta
and delta delta. There are 33 output labels: 26 letters, and the
apostrophe, period, dash, space, noise and sos/eos tokens.

All models are implemented using ESPnet [18]. For the
experiments on TIMIT, the encoder is a bidirectional LSTM
(BLSTM) layer on top of two pyramid BLSTM [19] layers
with 256 hidden units in each direction. The decoder is a one
layer LSTM with 512 hidden units. For the experiments on
WSJ, the encoder is two BLSTM layers on top of two pyramid
BLSTM layers with 320 hidden units in each direction. The
decoder is a one layer LSTM with 320 hidden units. We use the
AdaDelta [20] learning algorithm with gradient clipping. All
weights are initialized uniformly within the range \([-0.1, 0.1]\).
For decoding, we use a beam search with beam size 20.

### 3.1. Results and discussion on TIMIT

On the TIMIT data set, the results in Table 1 show our fully
trainable model outperforms the content-based attention base-
line significantly, reducing the phoneme error rate (PER) by
about 17% relative. Our model yields the best result when the
window size is trained by two separate MLPs,

When the window size is learned, we set a minimum window
size which covers 5 encoder hidden states (0.2s) – this
is key to successfully learning the step size. Without using a
minimum window size, the window sizes for some output units
shrink to zero quickly. Other methods, such as pre-training the
model with a fixed size window, making the window size MLP
share one bottom layer with the step size MLP, or setting both
the maximum step size and window size to a large value also
alleviate this problem. However, these methods do not gener-
ate the best results. Furthermore, if using a fixed size window
length of 0.2s, with the same maximum allowed step size, the
model fails completely and is unable to learn a meaningful
alignment vector, resulting in a very high PER.

As shown in Figure 2, the concatenation of two sigmoid
functions can predict the proper position of the window. How-
ever, this approach is worse than the baseline when the sigmoid
functions are flat within the window. Thus, if only provided
with the small window, and without a strong location con-
Fig. 2: Attention vectors generated by different constraint functions. The utterance is fgjd0_sx279 in the TIMIT development set (/sil ae l s ih z ah sil b ih l ah sil t iy sil t ah w er sil k w ih th aw sil s uw sil p er v ih sh ih n ih z n ow sil w er dh iy sil/).

We summarize the average step size and its standard deviation in Figure 3. Based on the statistics and our experiments using sigmoid window functions, we hypothesize two reasons for why a large window size is required when using a rule-based step size [8, 13]. First, the standard deviation is large. Thus, if the step size is fixed or rule-based, it will be often that the step size is smaller or bigger than the best step size. If the window size is small, then the most related source hidden states may not be included in the window. Second, even given the proper step size, our experiments indicate that without a strong location constraint within the window the attention mechanism is unable to generate the best alignment when the window size is small.

Fig. 3: The average learned step size for each phoneme and its standard deviation. The data is collected on TIMIT development set and test set.

3.2. Results and discussion on WSJ

On the WSJ dataset our model again outperforms the baseline but does not surpass the CTC-attention model (Table 2). We believe a major reason for this is that long pauses often occur in WSJ utterances. Thus, the maximum allowed step size and window size have to be relatively large so the model can jump over the silence part. However, large maximum window and step sizes are not optimal for non-silence parts.

For WSJ, we set both the maximum window size and step size to 1.32s, which is small compared to the window size (8.0s) in the rule-based method with a fixed step size [13]. Furthermore, except for the silence part, the learned step size and window size are much smaller than the maximum size. When combined with CTC, our model yields almost identical results to CTC-attention, but the computational requirements of the CTC-Gaussian attention approach are noticeably lower.

Since the utterances in WSJ begin with silence of varying lengths, and the silence part makes our model difficult to train, we pad the beginning of the text for each utterance with a padding word which is made of eight padding characters. This approach improves the performance of the content-based attention significantly. The lower part of Table 2 gives results for reduced subsets of the train_si284 training data, using 15k and 30k utterances.

Table 2: Character error rate (CER) on WSJ. Settings of the encoder-decoder and the optimizer are similar to [9]. After removing the padding characters in the decoding text generated by the baseline, the CER on eval92 is 7.5%, similar to CTC-attention without silence padding.

4. CONCLUSION

We have proposed a fully-trainable windowed attention mechanism. Compared to windowed attention approaches using a rule-based step size, our method learns a very small window and has competitive results. The proposed model outperforms the content-based attention on TIMIT and WSJ and has comparable results to CTC-attention on WSJ. We also find padding the silence part in the beginning of the utterances improves the performance of content-based models significantly. Our future work includes investigating our model on noisy data.
