INTRODUCTION

The endogenous cannabinoid (endocannabinoid) system is a complex network of receptors, a variety of ligands, and a series of enzymes that are responsible for ligand synthesis and breakdown. Endocannabinoids and their receptors are involved in the regulation of numerous physiological processes including neurotransmission, pain perception, learning, memory, cardiovascular homeostasis, appetite, motor function, and the immune response (reviewed in Klein et al., 2000; Grant and Cahn, 2005; Di Marzo, 1997; Kondo et al., 1998; Di Marzo et al., 2002; Ross, 2003; van der Stelt and Di Marzo, 2005; Tam et al., 2008). Endocannabinoids and their receptors play important roles in bone metabolism by regulating bone mass, bone loss, and bone cell function. This review summarizes in vivo and in vitro findings relating to the action of cannabinoid ligands in the skeleton.

THE SKELETAL ENDOCANNABINOID SYSTEM

CANNABINOID RECEPTOR LIGANDS IN BONE

Cannabinoid receptor ligands can be classified into three groups based on their source of production; endogenous cannabinoids, phytocannabinoids, and synthetic cannabinoids. Two of the best characterized endocannabinoids are N-arachidonoyl ethanolamine (anandamide) and 2-arachidonoylglycerol (2-AG). The endocannabinoids anandamide and 2-AG are responsible for most pharmacological actions associated with cannabinoid receptors in mammalian cells (reviewed in Pertwee, 2005). Anandamide and 2-AG are both derivatives of arachidonic acid and are produced from breakdown of glycerophospholipids in the cell membrane. Anandamide is synthesized from N-arachidonoyl phosphatidylycerolamine (NAPE) by the enzyme NAPE-phospholipase D (NAPE-PLD), whereas synthesis of 2-AG occurs through the action of phospholipase C (PLC) and the diacylglycerol lipases alpha and beta (DGALa and DGALB) on membrane phospholipids (Di Marzo et al., 1996; Maejima et al., 2001; Simon and Cravatt, 2006).

Once formed, endocannabinoids are transported across cell membranes by passive diffusion or endocytosis (for extensive review, refer to Fowler, 2012; Hermann et al., 2006). Anandamide and 2-AG are highly expressed in the brain and are also detected in a number of peripheral tissues including heart, liver, kidney, testis, and blood (Felder et al., 1993, 1996; Stella et al., 1997; Kondo et al., 1998; Di Marzo et al., 2002; Ross, 2003). Anandamide and 2-AG are responsible for most pharmacological actions associated with cannabinoid receptors in mammalian cells (reviewed in Klein et al., 2000; Grant and Cahn, 2005; Di Marzo, 1997; Kondo et al., 1998; Di Marzo et al., 2002). It should be noted, however, that FAAH is not specific for cannabinoids and degrades many other lipid containing molecules (Bauvarappaha, 2007).

There is evidence that the endocannabinoids 2-AG and anandamide are produced endogenously in the bone marrow and within the metabolically active trabecular compartment (Bah et al., 2008; Tam et al., 2008). A number of studies have shown that osteoblasts and osteoclasts are capable of producing anandamide and 2-AG in culture. Ridge et al. (2007) reported in abstract form that cultured osteoblast-like cells MC3T3-E1 and mouse osteoclasts produced 2-AG in vitro and that anandamide was produced by cultured osteoblasts but not osteoclasts. A recent study by the same group reported that the differentiation of human osteoclasts from monocytes is associated with a reduction in 2-AG levels and an increase in anandamide levels (Whyte et al., 2012). Rossi et al. (2009) reported that cultured human osteoclasts produced 2-AG and detectable quantities of anandamide; levels of both cannabinoids increased when the cultures were treated with the FAAH inhibitor URB597. Taken together, these observations indicate that 2-AG and anandamide are probably produced locally within bone and by bone cells in culture. In a study by Richardson et al. (2008), neither 2-AG nor anandamide were detected in synovial fluid from normal subjects, but both endocannabinoids...
Cannabinoid receptors are also present by plant derived cannabinoids. The Cannabis sativa plant contains a large number of phytocannabinoids such as Δ2-tetrahydrocannabinol (THC) which is an agonist at CB1 and CB2 receptors. It should be noted, however, that many psycho-cannabinoids such as cannabidiol bind weakly to cannabinoid receptors (reviewed by Mechoulam, 2005). A large number of synthetic cannabinoids have also been prepared some of which such as CP55,940, JWH-013, and HU2308 act as agonists thereby mimicking the action of endocannabinoids at a number of targets (Pertwee, 2005). On the other hand, a variety of synthetic compounds including SR141716A (also known as Rimonabant), AM251, and AM630 are described as inverse agonists/antagonists due to their ability to down-regulate the activity of cannabinoid receptors in the presence and absence of agonist binding (Gasley et al., 1996, 1997; Bouaboula et al., 1997; Hosokata et al., 1997a,b; Landsman et al., 1998; Lian et al., 1999; Ross et al., 1999; Mechler et al., 2000). For a comprehensive list of pharmacological properties of some of the most important cannabinoid receptor ligands refer to (Pertwee, 2005, 2010).

**CANNABINOID RECEPTORS IN BONE**

Endocannabinoids and their synthetic analogs bind to and activate two known cannabinoid receptors: CB1 and CB2 (Maccarrone and Finazzi-Agro, 2002; Pertwee and Ross, 2002). Recent studies suggest that the "orphan" G protein-coupled receptor GPR55 might represent a third cannabinoid receptor (Begg et al., 2005; Ryberg et al., 2007). The CB1 receptor, encoded by the CNR1 gene was the first cannabinoid receptor to be identified and it's mainly expressed in the brain (Matsuda et al., 1990). In the skeleton, CB2 receptors are expressed on nerve fibers intervening bone (Tam et al., 2006, 2008) and on cells of the immune system within the BM compartment (Klein et al., 2000, 2003). We and others reported that CB2 receptors are also present on osteoblasts, osteoclasts, and BM derived adipocytes at both protein and mRNA levels (Idris et al., 2009; Rossi et al., 2009). The CB2 receptor encoded by the CRN2 gene was originally identified in macrophages in the marginal zone of the spleen (Munro et al., 1993) but is now known to be expressed in many other tissues including bone and synovial joints as well as some regions of the central nervous system (Bouaboula et al., 1993; Galiou et al., 1995; Pertwee, 1997; Noiri et al., 2003; Klein et al., 2003; Idris et al., 2005; Ofek et al., 2006; Scutt and Williamson, 2007; Palacuelos et al., 2008). CB2 receptors are also expressed by osteoblasts, osteoclasts, and osteocytes at significantly higher level than that reported for CB1 (Idris et al., 2005; Ofek et al., 2006; Rossi et al., 2009; Whyte et al., 2012). Recent studies reported that bone cells including osteoblasts and osteoclasts also express GPR55 which is known to be targeted by endocannabinoids and synthetic cannabinoid ligands (Smart et al., 2000; Saunders et al., 2007; Abed et al., 2009; Rossi et al., 2009; Whyte et al., 2009). The GPR55 receptor encoded by the GPR55 gene is widely expressed but the highest levels are detected in the adrenals, the gastrointestinal tract, and the brain (Ryberg et al., 2007). It should be noted that cannabinoids such as anandamide can bind to other receptors such as nicotinic acetylcholine receptors, calcium channels, voltage-gated potassium channels, and transient receptor potential vanilloid receptors (TRPVs; Di Marzo et al., 2002; van der et al., 2003), although the physiological significance of this in the skeleton is unclear.

**CANNABINOID RECEPTOR SIGNALING IN BONE**

Cannabinoid receptors are a class of cell membrane receptors that belongs to the G protein-coupled receptor superfamily (Bouaboula et al., 1996; Ross et al., 1999). The CB1 receptor is constitutively active and therefore is able to transduce a biological signal in the absence of ligand (Carayon et al., 1998). Accordingly, cannabinoid receptor agonists inhibit adenylyl cyclase causing reduction in intracellular levels of cyclic adenosine monophosphate (cAMP; Demuth and Molleman, 2006). CB1 and CB2 receptors are also linked to a variety of other second messengers including nuclear factor of kappa B (NFκB), p38 mitogen-activated protein kinase (MAPK), intracellular signal-regulated kinases (ERKs), c-Jun N-terminal kinases (JNKs), PI3/Akt and focal adhesion kinase (FAK) phosphorylation (Derkinderen et al., 1996; Daika et al., 1997; Guzman et al., 2000b; Ho et al., 2002; Molina-Holgado et al., 2002; Sanchez et al., 2003; Karanian et al., 2005; Demuth and Molleman, 2006). The CB1 receptor has also been shown to couple to generation of the lipid second messenger ceramide by sphingomyelin hydrolysis and through de novo synthesis of ceramide (Guzman et al., 2001a). Cannabinoid receptor antagonists/inverse agonists such as the CB1 selective AM251 and CB2 selective AM630 block the effects of cannabinoid receptor agonists as well as down-regulate the constitutive activity of cannabinoid receptors in the absence of agonist binding (Bouaboula et al., 1997, 1999). Very little is known about the signaling mechanisms used by cannabinoid receptors to influence bone cell activity. There is evidence that the CB1 receptor regulates osteoblast and adipocyte differentiation by modulating intracellular cAMP levels (Idris et al., 2009). Moreover, recent studies showed that CB2 selective agonists induce mitogenic effects in osteoblasts via activation of a Gi protein-cyclin D1 and ERK1/2 axis (Ofek et al., 2011; Sophocleous et al., 2011). However, the mechanisms by which the CB1 and CB2 receptor regulate osteoclast differentiation and activity have not yet been fully clarified.

The GPR55 receptor is coupled to the G13 family of proteins (Gα13 and Gα12) rather than the Gαiγ proteins. The signaling pathways downstream of GPR55 have been less widely studied than CB1 and CB2 but ligand-induced activation of GPR55 has been shown to activate the small GTP binding proteins RhoA, Cdc42, and Rac1 (Ryberg et al., 2007), to trigger activation of the ERK/MEK signaling cascade (Kapur et al., 2009); to elicit release of intracellular calcium through activation of PLC/Laulker et al., 2008; Kapur et al., 2009) and to activate NFκB through effects on intracellular calcium (Ross, 2009). Activation of GPR55 with O-1602 and lysophosphatidylcholine (LPC) in osteoclasts has been reported to increase levels of active GTP-bound Rho and to stimulate ERK phosphorylation (Whyte et al., 2009).
REGULATION OF OSTEOCLASTIC BONE RESORPTION BY CANNABINOIDS

The classical cannabinoid receptors CB1 and CB2, and the orphan receptor GPR55 all play significant roles in the regulation of osteoclast function and bone resorption. Idris et al. (2005) were first to report that genetic inactivation of the CB1 receptor results in high peak bone mass in young mice. In this study, a detailed micro-computed tomography scanning of bone and histomorphometric analysis of bone formation and resorption revealed that mice deficient in CB1 receptor have less osteoclasts and reduced bone resorption (Idris et al., 2005). These findings have led to the realization that cannabinoid receptors play a significant role in the regulation of peak bone mass. In keeping with these observations, the CB1 selective antagonist/inverse agonists AM251 and SR141716A have been reported to cause osteoclast apoptosis and inhibit osteoclast formation in vitro and osteoclasts cultured from CB1 deficient mice were found to be resistant to the effects of AM251 indicating that the mechanism of osteoclast inhibition was mediated at least in part, by the CB1 receptor (Idris et al., 2005). Further studies have shown that the CB1 selective antagonist/inverse agonist AM630 inhibited osteoclastogenesis in murine and human cultures. In the same study, the CB2 selective ligands that strongly inhibited RANKL stimulated osteoclast formation over the concentration range 1–1000 nM (Idris et al., 2005, 2008). The reasons for this are unclear but possibilities include; species differences in responsiveness to AM630, off-target effects of AM630 at the high concentrations used or factors such as the choice of serum, some of which contain bioactive amounts of the endocannabinoid 2-AG sufficient to influence osteoclast differentiation and activity (Masarwa et al., 2011).

Recent studies have shown that the GPR55 receptor regulates osteoclast activity and bone resorption. A study by Whyte et al. (2009) showed that the GPR55 agonists 9-LP1 and O-1602 both inhibited osteoclast formation from bone marrow macrophages in vitro, whereas the GPR55 antagonist cannabidiol increased osteoclast formation. Although GPR55 agonists were found in this study to inhibit osteoclast formation, they actually stimulated the resorptive activity of osteoclasts. Conversely, the GPR55 antagonist cannabidiol enhanced osteoclast formation and inhibited resorptive activity. In keeping with these observations male mice with targeted inactivation of GPR55 were found to have increased numbers of osteoclasts in vivo, but these appeared unable to resorb bone effectively since trabecular bone mass was increased and carilage remnants at the growth plate were not resorbed efficiently. Rather surprisingly, female mice deficient in GPR55 were found to have reduced numbers of osteoclasts and increased amounts of unresorbed growth plate cartilage, but had normal bone mass (Whyte et al., 2009). Further studies in wild type mice revealed that cannabiol reduced levels of CTH – a biochemical marker of bone resorption – consistent with the in vitro observations. Taken together these observations indicate that activation of GPR55 inhibits osteoclast formation, but increases the ability of osteoclasts to resorb bone. Conversely, inhibition of GPR55 appears to increase osteoclast formation but reduces the ability of osteoclasts to resorb bone. The cannabinoid derivative auliacetic acid (AUA) which is structurally similar to both CBD and THC has been found to inhibit formation of multinucleated TRAP positive cells in RANKL treated RAW264.7 cultures and in M-CSF and RANKL treated bone marrow macrophages (George et al., 2008). The mechanism by which AUA regulates osteoclast formation is unclear since it has weak affinity for CB1 and presumably does not activate CB2 in view of the fact that it lacks psychotropic properties. Possibilities would include an effect on...
Fibroblast growth factor (FGF) receptor, which has recently been implicated in the regulation of osteoblast differentiation (Wan et al., 2007) or an effect on the GPR55 receptor.

In summary, there is evidence that both cannabinoid “classical” receptors CB1 and CB2 and the “orphan” receptor GPR55 regulate osteoblast activity and bone resorption. Conflictting results have been reported regarding the role of CB1 in regulating osteoblast differentiation in vitro with stimulatory effects reported by some workers and inhibitory effects by others. The reasons for these differences remain unclear at present but one explanation may be the fact that many cannabinoid receptor ligands have complex pharmacology and are not entirely specific for the cannabinoid receptors they were originally designed to target. For example, AM251, which was classically considered to be a selective CB1 receptor antagonist/inverse agonist has recently been reported to act as a GPR55 agonist (Lauckner et al., 2008, Ross, 2009). Perplexingly SR141716A has been reported to act as a GPR55 antagonist (Kapur et al., 2009) or agonist (Lauckner et al., 2008), depending on the assay system used. Similarly, the synthetic cannabinoid agonist CP55,940 has been shown to be act as a GPR55 agonist/partial agonist and JWH015, formerly considered a specific CB2 agonist has been shown to be a GPR55 agonist (Kapur et al., 2009). These data indicate that the interpretation of some ligand activities previously attributed to effects on the CB1 or CB2 receptors may have been confounded by effects on the GPR55 receptor. Further research will clearly be required to investigate these issues and to explore the relative roles that CB1, CB2, and GPR55 play in regulating osteoblast differentiation and function.

REGULATION OF OSTEOBLAST FUNCTION AND BONE FORMATION BY CANNABINOIDS

Endocannabinoids and their receptors are involved in the regulation of osteoblast differentiation and bone formation. Mice with targeted deletion of the CB1 receptor have been found to develop osteoporosis with increasing age due to reduced bone formation and accumulation of adipocytes in the bone marrow space (Idris et al., 2009). Other research has shown that CB1 receptors are present on preosteoblast cultures. In view of this it seems unlikely that GPR55 regulates osteoblast differentiation in vivo (Idris et al., 2009). Other research has shown that the CB1 receptor plays a key role in regulating the increased bone formation that accompanies traumatic brain injury (TBI). This was investigated by Tan et al. (2008) who reported that the expected increase in bone formation following TBI was absent in CB1 deficient mice, but was present in wild type and CB2 deficient mice. In this study, Tan et al. (2008) also reported that TBI induced bone formation in wild type mice was abolished by the beta adrenergic receptor agonist isoproterenol. This led the authors to speculate that CB1 receptors present on presynaptic nerve endings in bone might enhance bone formation by suppressing catecholamine release (Tam et al., 2008). Although this is a plausible hypothesis, the experiments conducted did not determine whether the effect of the CB1 receptor on bone formation was truly mediated by this sequence of events or not. Other studies by the same authors (Tam et al., 2006) showed that bone formation rate and mineral apposition rate were reduced in young (9–12-week old) CB1 deficient mice on a CD1 background; again confirming that CB1 appears to play a key role in regulating bone formation. Recent findings have shown that the CB1 receptor plays a role in glucocorticoid-induced bone loss (Wu et al., 2011; Ko et al., 2012). CB1 blockage attenuated the deleterious actions of glucocorticoid treatment on osteoblast activity and bone formation, significantly reduced bone loss and abrogated marrow adiposity (Wu et al., 2011; Ko et al., 2012). Mechanistic studies revealed that CB1 regulates glucocorticoid-induced dysfunction in osteoblasts via activation of a number of pathways including PI3/Akt, MAPK and runt-related transcription factor 2 and peroxisome proliferator-activated receptor 2 (Wu et al., 2011; Ko et al., 2012).

The CB2 receptor also plays a role in regulating bone formation. The CB2 selective agonists HU308, JWH133, and JWH15 have all been shown to stimulate bone nodule formation in bone marrow stromal cell cultures in vitro, although similar effects have been observed with non-selective agonists including anandamide, 2-AG, CP55,940, and WIN 55,212 (O36k et al., 2006; Scott and Williamson, 2009; Idris et al., 2009). A specific role for CB2 receptors in mediating these effects is supported by the fact that bone marrow stromal cells from CB2 deficient mice have a reduced capacity to differentiate into bone nodules when compared with those of wild type littermates. Although mice with targeted inactivation of CB2 have increased bone turnover, there is a relative defect in bone formation as evidenced by the fact that CB2 deficient mice develop age-related osteoporosis (O36k et al., 2006). This is consistent with a model whereby CB2 is required for maintenance of normal bone formation in high bone turnover states.

The role of the GPR55 receptor on bone formation has not been extensively studied, but Whyte et al. (2009) found no significant abnormalities in histomorphometric indices of bone formation in GPR55 knockout mice and also reported that the GPR55 agonist O-1602 had little effect on bone nodule formation in mouse calvarial osteoblast cultures. In view of this it seems unlikely that GPR55 plays a major role in regulating bone formation. Several phyto-cannabinoids including cannabidiol, cannabinol, cannabidivarin, THC2, and tetrahydrocannabivarin (THCV) have been reported to stimulate bone nodule formation, collagen production, and alkaline phosphatase activity in cultures of bone marrow stromal cells (Scott and Williamson, 2007). At the present time, however, it is unclear to what extent these compounds are acting through cannabinoid receptors or other molecular targets. For example the phytocannabinoid THCV which was found in the above study to promote bone nodule formation is known to act as an antagonist of CB1 and CB2 receptors, which would be expected to reduce bone formation.
formation, according to the studies that have been performed in genetically modified mice (Ofek et al., 2006; Tam et al., 2006; Idris et al., 2009). In view of this it is clear that further research will be required to fully investigate the mechanisms by which these phytocannabinoids regulate bone cell activity.

In summary, current evidence suggests that both the CB1 and CB2 receptors play significant roles in regulating osteoblast differentiation and bone formation in response to TBI and ageing. The fact that CB1 knockout mice develop accumulation of marrow fat also suggests that the CB1 receptor regulates the age-related "switch" in differentiation potential of bone marrow stromal cells (Gimble et al., 2006).

REGULATION OF BONE MASS BY CANNABINOID RECEPTORS

A number of genetic and pharmacological studies have reported that cannabinoid receptors regulate bone mass in health and disease. Mice with deletion of the CB1, CB2, and GPR55 receptors all exhibit abnormalities of bone mass although this is dependent to an extent, on background strain, gender and age. The first report of an abnormality in bone mass in relation to the endocannabinoid system came from the studies of Idris and colleagues who reported that female CB1 deficient mice on inbred (ABH) and outbred (CD1) backgrounds exhibited high peak bone mass affecting the trabecular compartment of bone (Idris et al., 2005). This was found to be due to a defect in osteoclastic bone resorption and in keeping with this, CB1 deficient mice were found to be resistant to ovariectomy induced bone loss (Idris et al., 2005). In a subsequent study, Idris et al. (2009) demonstrated that the high peak bone mass in CB1 deficient mice was found in both genders, and went on to show that CB1 deficient mice developed marked trabecular osteoporosis with increasing age due to a defect in bone formation and accumulation of marrow fat. Remarkably, this age-related bone loss occurred despite the fact that osteoclastic bone resorption remained lower in CB1 deficient mice than in wild type littermates throughout life. In another study Tam et al. (2006) confirmed that CB1 deficient mice on a CD1 background had high peak bone mass. Although this was observed in both genders, the difference was significant only for male mice. In stark contrast to these findings, CB1 deficient mice on a C57BL/6 background were found by Tam et al. (2006) to have reduced peak bone mass when compared with wild type littermates. The molecular mechanisms for these differences remain to be fully explored but they are probably related to polymorphisms or mutations in genes that interact with cannabinoid receptors to regulate cellular responses in different mouse strains. Abnormalities of bone mass have also been described in CB1 deficient mice. The first report came from Ofek et al. (2006) who found no major abnormalities of bone mass in young (8-week old) mice, but found that by 51 weeks of age, the CB1 deficient mice had developed marked trabecular osteoporosis with cortical expansion. Histomorphometric examination showed evidence of high bone turnover indicating that the likely mechanisms of bone loss was relative uncoupling of bone resorption and bone formation (Ofek et al., 2006). Idris et al. (2008) also found that peak bone mass was relatively normal in CB1 deficient mice and recent studies have shown these mice develop age-related osteoporosis (Sopodouces et al., 2011). In a recent study, Sophocleous et al. (2012) have reported in an abstract form that combined deficiency of the CB1 and CB2 receptors enhances peak bone mass but increases age-related bone loss. At 3 months of age, female CD1 mice deficient in both CB1 and CB2 receptors had significantly higher peak bone mass than wild type controls due to a significant decrease in osteoclast number and activity. Interestingly, these differences in peak bone mass and bone resorption observed were quantitatively similar to those previously observed in single knockouts of CB1 (Idris et al., 2005, 2009) and CB2 (Sophocleous et al., 2012) in the same background. By 12 months of age female deficient in both CB1 and CB2 receptors had significantly lower trabecular bone mass and histomorphometric analysis showed that this was associated with a dramatic increase in bone marrow fat accumulation and a reduction in osteoblast numbers and bone formation rate compared to wild type controls of similar age. The differences in bone mass and bone cell activity that the authors observed in female deficient in both CB1 and CB2 receptors were quantitatively similar to those previously observed in single knockouts of CB1 but not CB2 (Idris et al., 2009). Altogether, these data indicate that combined CB1 and CB2 deficiency enhances peak bone mass by an effect on bone resorption but predisposes to age-related osteoporosis by promoting adipocyte differentiation at the expense of osteoblast differentiation in the bone marrow compartment. This study demonstrates that CB1 and CB2 have overlapping but distinctive roles in skeletal homeostasis and show that CB1 in particular plays a key role in regulating osteoblast and adipocyte differentiation in the bone marrow compartment. Mice with targeted inactivation of the GPR55 receptor have been reported to have high peak bone mass affecting the trabecular compartment of the tibia and femur, but interestingly this was only noted in male mice (Whyte et al., 2009). The mechanism seemed to be impairment of bone resorption; although the reasons responsible for the gender difference in skeletal phenotype in these animals remains unclear at present.

FUTURE RESEARCH DIRECTIONS

There is a steadily growing body of evidence suggesting that the skeletal endocannabinoid system plays a significant role in regulating bone mass and bone turnover. Several outstanding questions remain unanswered however. One is to define the mechanisms by which endocannabinoid production in bone is regulated and specifically to determine if it is influenced by classical calcium regulating hormones, cytokines and mechanical loading. Further research is also required to fully define the signaling pathways used by these receptors to regulate bone cell activity. There is evidence to suggest that the CB1 receptor regulates osteoblast and adipocyte differentiation through a cAMP-mediated pathway but little is known about the mechanisms by which cannabinoids regulate osteoclast activity. There have been major discrepancies between different studies with regard to the effects of different cannabinoid receptor ligands on osteoclast differentiation and function. These remain to be completely resolved but some of the discrepancies between studies could be due to the fact that many cannabinoid receptor ligands which were previously thought to be specific for CB1 and/or CB2 have now been shown to have effects on GPR55 signaling (Kapur et al., 2009;...
Pertwee, R., Ross, 2009). A further area of research which remains to be explored is to determine to what extent the CB1 receptor exerts its effects on the skeleton by a central (neu- ronal) or peripheral mechanism. This is clinically relevant since if the peripheral effects were predominant, it may be possible to develop agonists of CB1 that do not cross the blood brain barrier but influence bone formation without causing adverse psychotropic effects. The outcome of these studies will greatly enhance our understanding of the role of the skeletal endocannabinoid system in bone remodeling and encourage the development of new treatments for bone diseases based on targeting cannabinoid receptors.

Role of cannabinoids in the regulation of bone remodeling

Cannabinoids are a class of compounds that bind to cannabinoid receptors (CB1 and CB2) to modulate various physiological processes, including bone remodeling. In recent years, the role of cannabinoids in bone metabolism has been extensively studied.

Cannabinoids have been shown to influence bone formation and resorption through interactions with cannabinoid receptors expressed on osteoblasts, osteoclasts, and other bone cells. For example, the cannabinoid CB1 receptor has been implicated in the regulation of bone turnover, as its activation can lead to increased bone resorption.

Moreover, cannabinoid CB2 receptors are found on osteoclasts and may play a role in the negative feedback mechanisms that control bone remodeling. Studies have shown that cannabinoid CB2 receptor agonists can inhibit bone resorption and stimulate bone formation.

In addition to their direct effects on bone cells, cannabinoids may also influence bone remodeling through systemic effects. For instance, the endocannabinoid anandamide is a full agonist at the CB1 cannabinoid receptor and can modulate bone remodeling by acting on osteoblasts and osteoclasts.

These findings suggest that cannabinoids may have therapeutic potential in the treatment of bone disorders, such as osteoporosis and osteoarthritis. Further research is needed to fully understand the mechanisms by which cannabinoids regulate bone metabolism and to develop new cannabinoid-based therapies for bone-related diseases.

Cannabinoid receptor 1 regulates ERK and GSK-3beta-dependent glucocorticoid inhibition of osteoblast differentiation in murine MC3T3-E1 cells. Bone 49, 1205–1213.

Conflict of Interest Statement: The authors are co-inventors on patents claiming the use of cannabinoid receptor ligands as treatments for bone disease.
