The endocannabinoid system plays a key role in regulating a variety of physiological processes such as appetite control and energy balance, pain perception, and immune responses. Recent studies have implicated the endocannabinoid system in the regulation of bone cell activity and bone remodeling. These studies showed that endogenous cannabinoid ligands, cannabinoid receptors, and the enzymes responsible for ligand synthesis and breakdown all play important roles in bone mass and in the regulation of bone disease. These findings suggest that the endocannabinoid pathway could be of value as a therapeutic target for the prevention and treatment of bone diseases. Here, we review the role of the skeletal endocannabinoid system in the regulation of bone remodeling in health and disease.

Keywords: cannabinoid, Bone, CB1, CB2, GPR55, Osteoblasts, Osteoclasts, Adipocytes

INTRODUCTION

The endogenous cannabinoid (endocannabinoid) system is a complex network of receptors, a variety of ligands, and a series of enzymes that are responsible for ligand synthesis and breakdown. Endocannabinoids and their receptors are involved in the regulation of numerous physiological processes including neurotransmission, pain perception, learning, memory, cardiovascular homeostasis, appetite, motor function, and the immune response (reviewed in Klein et al., 2000; Grant and Cahn, 2005; Di Marzo, 2008). There is accumulating evidence to suggest that endocannabinoids and their receptors play important roles in bone metabolism by regulating bone mass, bone loss, and bone cell function. This review summarizes in vitro and in vivo findings relating to the action of cannabinoid ligands in the skeleton.

THE SKELETAL ENDOCANNABINOID SYSTEM

CANNABINOID RECEPTOR LIGANDS IN BONE

Cannabinoid receptor ligands can be classified into three groups based on their source of production: endogenous cannabinoids (endocannabinoids), phytocannabinoids, and synthetic cannabinoids. Two of the best characterized endocannabinoids are N-arachidonoyl phosphatidylethanolamine (anandamide) and 2-arachidonoylglycerol (2-AG). The endocannabinoids anandamide and 2-AG are responsible for most pharmacological actions associated with cannabinoid receptors in mammalian cells (reviewed in Pertwee, 2005). Anandamide and 2-AG are both derivatives of arachidonic acid and are produced from breakdown of glycerophospholipids in the cell membrane. Anandamide is synthesized from N-arachidonoyl phosphatidylethanolamine (NAPE) by the enzyme NAPE-phospholipase D (NAPE-PLD), whereas synthesis of 2-AG occurs through the action of phospholipase C (PLC) and the diacylglycerol lipases alpha and beta (DAGLα and DAGLβ) on membrane phospholipids (Di Marzo et al., 1996; Maejima et al., 2001a,b; Simon and Cravatt, 2006). Once formed, endocannabinoids are transported across cell membranes by passive diffusion or endocytosis (for extensive review, refer to Fowler, 2012; Hermann et al., 2006). Anandamide and 2-AG are highly expressed in the brain and are also detected in a number of peripheral tissues including heart, liver, kidney, testis, and blood (Földi et al., 1993, 1996; Stella et al., 1997; Kondo et al., 1998; Di Marzo et al., 1999, 2000; Ross, 2003; van der Stelt and Di Marzo, 2005; Tam et al., 2008). Endocannabinoids have a short half life due to the fact that they are rapidly degraded by a variety of enzymes including fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL; Dinh et al., 2002). It should be noted, however, that FAAH is not specific for cannabinoids and degrades many other lipid containing molecules (Basavarajappa, 2007).

There is evidence that the endocannabinoids 2-AG and anandamide are produced endogenously in the bone marrow and within the metabolically active trabecular compartment (Bab et al., 2008; Tam et al., 2008). A number of studies have shown that osteoblasts and osteoclasts are capable of producing anandamide and 2-AG in culture. Ridge et al. (2007) reported in abstract form that cultured osteoblast-like cells MC3T3-E1 and mouse osteoclasts produced 2-AG in vitro and that anandamide was produced by cultured osteoblasts but not osteoclasts. A recent study by the same group reported that the differentiation of human osteoclasts from monocytes is associated with a reduction in 2-AG levels and an increase in anandamide levels (Whyte et al., 2012). Rossi et al. (2009) reported that cultured human osteoclasts produced 2-AG and detectable quantities of anandamide; levels of both cannabinoids increased when the cultures were treated with the FAAH inhibitor URB597. Taken together, these observations indicate that 2-AG and anandamide are probably produced locally within bone and by bone cells in culture. In a study by Richard-son et al. (2008), neither 2-AG nor anandamide were detected in synovial fluid from normal subjects, but both endocannabinoids...
Cannabinoid receptors are also linked to a variety of mechanisms used by cannabinoid receptors to influence bone cell activity. There is evidence that the CB2 receptor regulates osteoblast and adipocyte differentiation by modulating intracellular cAMP levels (Idris et al., 2009). Moreover, recent studies showed that CB2 selective agonists induce mitogenic effects in osteoblasts via activation of a G protein-cyclin D1 and ERK1/2 axis (Olive et al., 2011; Sophocleous et al., 2011). However, the mechanisms by which the CB1 and CB2 receptors regulate osteoclast differentiation and activity have not yet been fully clarified.

The GPR55 receptor is coupled to the G_{12/13} family of proteins (Gα_{12} and Gα_{13}) rather than the G_{i} proteins. The signaling pathways downstream of GPR55 have been less widely studied than CB1 and CB2 but ligand-induced activation of GPR55 has been shown to activate the small GTP binding proteins RhoA, Cdc42, and Rac1 (Ryberg et al., 2007), to trigger activation of the ERK/MAF signaling cascade (Kapur et al., 2009); to elicit release of intracellular calcium through activation of PLC/Luckner et al., 2008; Kapur et al., 2009) and to activate NFκB through effects on intracellular calcium (Ross, 2009). Activation of GPR55 with O-1602 and lysophosphatidylinositol (LPI) in osteoclasts has been reported to increase levels of active GTP-bound Rho and to stimulate ERK phosphorylation (Whyte et al., 2009).
REGULATION OF OSTEOCLASTIC BONE RESORPTION BY CANNABINOIDS

The classical cannabinoid receptors CB1 and CB2, and the orphan receptor GPR55 all play significant roles in the regulation of osteoclast function and bone resorption. Idris et al. (2005) were first to report that genetic inactivation of the CB1 receptor results in high peak bone mass in young mice. In this study, a detailed micro-computed tomography scanning of bone and histomorphometric analysis of bone formation and resorption revealed that mice deficient in CB1 receptor have less osteoclasts and reduced bone resorption (Idris et al., 2005). These findings have led to the realization that cannabinoid receptors play a significant role in the regulation of peak bone mass. In keeping with these observations, the CB1 selective antagonist/inverse agonists AM251 and SR141716A have been reported to cause osteoclast apoptosis and inhibit osteoclast formation in vitro and osteoclasts cultured from CB1 deficient mice were found to be resistant to the effects of AM251 indicating that the mechanism of osteoclast inhibition was mediated at least in part, by the CB1 receptor (Idris et al., 2005). Further studies have shown that the CB1 selective antagonist/inverse agonist AM251 (1–3mg/kg/day) prevents ovariectomy induce bone loss in wild type mice and that CB1 deficient mice are resistant to ovariectomy-induced bone loss, findings which support the view that activation of the CB1 receptor promotes osteoclast differentiation and bone resorption (Idris et al., 2005).

There is evidence that the defect in osteoclast formation in CB1 deficient mice is caused both, by a reduction in the sensitivity of osteoclast precursors to RANKL and a reduction in the ability of CB1 deficient osteoclasts to support osteoclast formation due to reduced RANKL expression (Idris et al., 2009).

The CB2 receptor also regulates osteoclast activity and bone resorption, but research in this area to date has yielded rather contradictory results. Ofek et al. (2016) reported that CB2 deficient mice developed osteoporosis with increasing age due to increased bone turnover. In keeping with these findings, it was reported in the same study that the CB2 selective agonist HU308 inhibited RANKL-induced osteoclast formation in bone marrow and RAW 264.7 cultures in vitro. In complete contrast to these findings, Idris and colleagues reported, that anandamide and 2-AG, HU308 and JWH133 enhanced M-CSF- and RANKL-induced osteoclast formation over the concentration range 1–1000 nM (Idris et al., 2005), whereas the CB2 selective agonist/inverse agonist AM630 was inhibitory (Idris et al., 2005, 2008). Further studies by Idris et al. (2008) showed that bone marrow cells isolated from CB2 deficient mice produce fewer osteoclasts in response to RANKL than wild type controls and that CB2 deficient mice were partially protected from ovariectomy-induced bone loss as compared with wild type littermates. In agreement with these observations others have reported that the endocannabinoids 2-AG and anandamide were found to stimulate bone resorption by human osteoclasts in vitro (Ridge et al., 2007; Whyte et al., 2012). Schauhly et al. (2011) have recently introduced a new class of highly CB2 selective ligands that strongly inhibited RANKL stimulated osteoclastogenesis in murine and human cultures. In the same study, the authors went to demonstrate that endocannabinoids stimulate osteoclast formation and these effects were significantly inhibited by natural biphenyl neolignan derivatives (Schauhly et al., 2011). In vivo, Idris et al. (2008) showed that the CB2 selective antagonist/inverse agonist AM630 prevents from ovariectomy-induced bone loss in a CB2 dependent and independent manner depending on administered dose. In broad agreement with this, Gein et al. (2010) showed that AM630 protected against the development of titanium particle induced osteolytic bone loss by reducing osteoclastogenesis. Furthermore, Lunn et al. (2007) reported that the novel CB2 selective agonist Sch.036 prevented bone damage in arthritic mice. Taken together these studies indicate that pharmacological inhibition of the CB2 receptor inhibits osteoclast formation and reduces bone loss in adult mice. However, Rossi et al. (2009) reported that the CB2 selective antagonist/inverse agonist AM630 at high concentrations (10 μM) stimulated human osteoclast formation. The stimulatory effects of AM630 on osteoclast formation in human cultures reported by Rossi and colleagues are exactly opposite to the inhibitory effects if AM630 on osteoclast formation in mouse cultures reported by Idris et al. (2005, 2008). The reasons for this are unclear but possibilities include; species differences in responsiveness to AM630, off-target effects of AM630 at the high concentrations used or factors such as the choice of serum, some of which contain bioactive amounts of the endocannabinoid 2-AG sufficient to influence osteoclast differentiation and activity (Musazzi et al., 2011).

Recent studies have shown that the GPR55 receptor regulates osteoclast activity and bone resorption. A study by Whyte et al. (2009) showed that the GPR55 agonists L-α-LPI and O-1602 both inhibited osteoclast formation from bone marrow macrophages in vitro, whereas the GPR55 antagonist cannabidiol increased osteoclast formation. Although GPR55 agonists were found in this study to inhibit osteoclast formation, they actually stimulated the resorptive activity of osteoclasts. Conversely, the GPR55 antagonist cannabidiol enhanced osteoclast formation and inhibited resorptive activity. In keeping with these observations male mice with targeted inactivation of GPR55 were found to have increased numbers of osteoclasts in vivo, but these appeared unable to resorb bone effectively since trabecular bone mass was increased and cartilage remnants at the growth plate were not resorbed efficiently. Rather surprisingly, female mice deficient in GPR55 were found to have reduced numbers of osteoclasts and increased amounts of unresorbed growth plate cartilage, but had normal bone mass (Whyte et al., 2009). Further studies in wild type mice revealed that cannabidiol reduced levels of CTX – a biochemical marker of bone resorption – consistent with the in vitro observations. Taken together these observations indicate that activation of GPR55 inhibits osteoclast formation, but increases the ability of osteoclasts to resorb bone. Conversely, inhibition of GPR55 appears to increase osteoclast formation but reduces the ability of osteoclasts to resorb bone. The cannabinoid deriva-

4
PPARγ, which has recently been implicated in the regulation of osteoblast differentiation (Wan et al., 2007) or an effect on the GPR55 receptor.

In summary, there is evidence that both cannabinoid “classical” receptors CB1 and CB2 and the “orphan” receptor GPR55 regulate osteoblast activity and bone resorption. Conflicting results have been reported with regard to the role of CB1 in regulating osteoblast differentiation in vitro with stimulatory effects reported by some workers and inhibitory effects by others. The reasons for these differences remain unclear at present but one explanation may be the fact that many cannabinoid receptor ligands have complex pharmacology and are not entirely specific for the cannabinoid receptors they were originally designed to target. For example, AM251, which was classically considered to be a specific CB1 selective antagonist/inverse agonist has recently been reported to act as a GPR55 agonist (Lauckner et al., 2008, Ross, 2008). Perplexingly SR141716A has been reported to act as a GPR55 antagonist (Kapur et al., 2009) or agonist (Lauckner et al., 2008), depending on the assay system used. Similarly, the synthetic cannabinoid agonist CP55,940 has been shown to act as a GPR55 agonist (Kapur et al., 2009). These data indicate that the interpretation of some ligand activities previously attributed to effects on the CB1 or CB2 receptors may have been confounded by effects on the GPR55 receptor. Further research will clearly be required to investigate these issues and to explore the relative roles that CB1, CB2, and GPR55 play in regulating osteoblast differentiation and function.

REGULATION OF OSTEOBLAST FUNCTION AND BONE FORMATION BY CANNABINOIDS

Endocannabinoids and their receptors are involved in the regulation of osteoblast differentiation and bone formation. Mice with targeted deletion of the CB1 receptor have been found to develop osteoporosis with increasing age due to reduced bone formation and accumulation of adipocytes in the bone marrow space (Idris et al., 2009). In these studies, bone marrow stromal cells from CB1 deficient mice had an increased capacity for adipocyte differentiation and a reduced capacity for osteoblast differentiation and these effects were reproduced by treatment of wild type mice with the CB1 receptor antagonist/inverse agonist AM251 (Idris et al., 2009). Furthermore, the CB1 selective antagonist/inverse agonist AM251 was found to block the stimulatory effect of CP55,940 on bone nodule formation in vitro (Idris et al., 2008). Signaling studies have shown that blockade of CB1 receptors with AM251 in osteoblast like cells and preadipocytes up-regulated cAMP, stimulated CREB phosphorylation, inhibited expression of the osteoblast-specific transcription factor Runx2 and increased expression of the adipocyte-specific transcription factor PPARγ (Idris et al., 2009). Other research has shown that the CB1 receptor plays a key role in regulating the increased bone formation that accompanies traumatic brain injury (TBI).

This was investigated by Tam et al. (2008) who reported that the expected increase in bone formation following TBI was absent in CB1 deficient mice, but was present in wild type and CB2 deficient mice. In this study, Tam et al. (2008) also reported that TBI induced bone formation in wild type mice was abolished by the beta adrenergic receptor agonist isoprotrenol. This led the authors to speculate that CB1 receptors present on presynaptic nerve endings in bone might enhance bone formation by suppressing catecholamine release (Tam et al., 2008). Although this is a plausible hypothesis, the experiments conducted did not determine whether the effect of the CB1 receptor on bone formation was truly mediated by this sequence of events or not. Other studies by the same authors (Tam et al., 2006) showed that bone formation rate and mineral apposition rate were reduced in young (9–12-week old) CB1 deficient mice on a CD1 background, again confirming that CB1 appears to play a key role in regulating bone formation. Recent findings have shown that the CB1 receptor plays a role in glucocorticoid-induced bone loss (Wu et al., 2011; Ko et al., 2012). CB1 blockade attenuated the deleterious actions of glucocorticoid treatment on osteoblast activity and bone formation, significantly reduced bone loss and abrogated marrow adiposity (Wu et al., 2011; Ko et al., 2012). Mechanistic studies revealed that CB1 regulates glucocorticoid-induced dysfunction in osteoblasts via activation of a number of pathways including PI3/Akt, MAPK and runt-related transcription factor 2 and peroxisome proliferator-activated receptor 2 (Wu et al., 2011; Ko et al., 2012).

The CB2 receptor also plays a role in regulating bone formation. The CB2 selective agonists HU308, JWH133, and JWH15 have all been shown to stimulate bone nodule formation in bone marrow stromal cell cultures in vitro, although similar effects have been observed with non-selective agonists including anandamide, 2-AG, CP55,940, and WIN 55,212 (Ofek et al., 2006; Scutt and Williamson, 2007; Idris et al., 2009). A specific role for CB2 receptors in mediating these effects is supported by the fact that bone marrow stromal cells from CB2 deficient mice have a reduced capacity to differentiate into bone nodules when compared with those of wild type littermates. Although mice with targeted inactivation of CB2 have increased bone turnover, there is a relative defect in bone formation as evidenced by the fact that CB2 deficient mice develop age-related osteoporosis (Ofek et al., 2006). This is consistent with a model whereby CB2 is required for maintenance of normal bone formation in high bone turnover states.

The role of the GPR55 receptor on bone formation has not been extensively studied, but Whyte et al. (2009) found no significant abnormalities in histomorphometric indices of bone formation in GPR55 knock out mice and also reported that the GPR55 agonist O-1602 had little effect on bone nodule formation in mouse calvarial osteoblast cultures. In view of this it seems unlikely that GPR55 plays a major role in regulating bone formation. Several phyto- cannabinoids including cannabidiol, cannabinol, cannabinodivarin, THCαc, and tetrahydrocannabinol (THCV) have been reported to stimulate bone nodule formation, collagen production, and alkaline phosphatase activity in cultures of bone marrow stromal cells (Scutt and Williamson, 2007). At the present time, however, it is unclear to what extent these compounds are acting through cannabinoid receptors or other molecular targets. For example the phytoannabinoid THCV which was found in the above study to promote bone nodule formation is known to act as an antagonist of CB1 and CB2 receptors, which would be expected to reduce bone formation.
formation, according to the studies that have been performed in genetically modified mice (Ofek et al., 2006; Tam et al., 2006; Idris et al., 2009). In view of this it is clear that further research will be required to fully investigate the mechanisms by which these phytocannabinoids regulate bone cell activity.

In summary, current evidence suggests that both the CB1 and CB2 receptors play significant roles in regulating osteoblast differentiation and bone formation in response to TBI and ageing. The fact that CB1 knockout mice develop accumulation of marrow fat also suggests that the CB1 receptor regulates the age-related "switch" in differentiation potential of bone marrow stromal cells (Gimble et al., 2006).

REGULATION OF BONE MASS BY CANNABINOID RECEPTORS

A number of genetic and pharmacological studies have reported that cannabinoid receptors regulate bone mass in health and disease. Mice with deletion of the CB1, CB2, and GPR55 receptors all exhibit abnormalities of bone mass although this is dependent on strain, background, gender and age. The first report of an abnormality in bone mass in relation to the endocannabinoid system came from the studies of Idris and colleagues who reported that female CB1 deficient mice on inbred (AB1) and outbred (CD1) backgrounds exhibited high peak bone mass affecting the trabecular compartment of bone (Idris et al., 2005). This was found to be due to a defect in osteoclastic bone resorption and in keeping with this, CB1 deficient mice were found to be resistant to ovariectomy induced bone loss (Idris et al., 2005).

In a subsequent study, Idris et al. (2009) demonstrated that the high peak bone mass in CB1 deficient mice was found in both genders, and went on to show that CB1 deficient mice developed marked trabecular osteoporosis with increasing age due to a defect in bone formation and accumulation of marrow fat. Remarkably, this age-related bone loss occurred despite the fact that osteoclastic bone resorption remained lower in CB1 deficient mice than in wild type littersmates throughout life. In another study Tam et al. (2006) confirmed that CB2 deficient mice on a CD1 background had high peak bone mass. Although this was observed in both genders, the difference was significant only for male mice. In stark contrast to these findings, CB1 deficient mice on a C57Bl/6 background were found by Tam et al. (2006) to have reduced peak bone mass when compared with wild type littersmates. The molecular mechanisms for these differences remain to be fully explored but they are probably related to polymorphisms or mutations in genes that interact with cannabinoid receptors to regulate cellular responses in different mouse strains. Abnormalities of bone mass have also been described in CB2 deficient mice. The first report came from Ofek et al. (2006) who found no major abnormalities of bone mass in young (8-week old) mice, but found that by 51 weeks of age, the CB2 deficient mice had developed marked trabecular osteoporosis with cortical expansion. Histomorphometric examination showed evidence of high bone turnover indicating that the likely mechanisms of bone loss was relative uncoupling of bone resorption and bone formation (Ofek et al., 2006). Idris et al. (2008) also found that peak bone mass was relatively normal in CB2 deficient mice and recent studies have shown these mice develop age-related osteoporosis (Sophodeous et al., 2011).

In a recent study, Sophodeous et al. (2012) have reported in an abstract form that combined deficiency of the CB1 and CB2 receptors enhances peak bone mass but increases age-related bone loss. At 3 months of age, female CD1 mice deficient in both CB1 and CB2 receptors had significantly higher peak bone mass than wild type controls due to a significant decrease in osteoclast number and activity. Interestingly, these differences in peak bone mass and bone resorption observed were quantitatively similar to those previously observed in single knockouts of CB1 (Idris et al., 2005, 2009) and CB2 (Sophodeous et al., 2012) in the same background. By 12 months of age female deficient in both CB1 and CB2 receptors had significantly lower trabecular bone mass and histomorphometric analysis showed that this was associated with a dramatic increase in bone marrow fat accumulation and a reduction in osteoblast numbers and bone formation rate compared to wild type controls of similar age. The differences in bone mass and bone cell activity that the authors observed in female deficient in both CB1 and CB2 receptors were quantitatively similar to those previously observed in single knockouts of CB1 but not CB2 (Idris et al., 2009). Altogether, these data indicate that combined CB1 and CB2 deficiency enhances peak bone mass by an effect on bone resorption but predisposes to age-related osteoporosis by promoting adipocyte differentiation at the expense of osteoblast differentiation in the bone marrow compartment. This study demonstrates that CB1 and CB2 have overlapping but distinctive roles in skeletal homeostasis and show that CB1 in particular plays a key role in regulating osteoblast and adipocyte differentiation in the bone marrow compartment. Mice with targeted inactivation of the GPR55 receptor have been reported to have high peak bone mass affecting the trabecular compartment of the tibia and femur, but interestingly this was only noted in male mice (Whyte et al., 2009). The mechanism seemed to be impairment of bone resorption; although the reasons responsible for the gender difference in skeletal phenotype in these animals remains unclear at present.

FUTURE RESEARCH DIRECTIONS

There is a steadily growing body of evidence suggesting that the skeletal endocannabinoid system plays a significant role in regulating bone mass and bone turnover. Several outstanding questions remain unanswered however. One is to define the mechanisms by which endocannabinoid production in bone is regulated and specifically to determine if it is influenced by classical calcium regulating hormones, cytokines and mechanical loading. Further research is also required to fully define the signaling pathways used by these receptors to regulate bone cell activity. There is evidence to suggest that the CB1 receptor regulates osteoblast and adipocyte differentiation through a cAMP-mediated pathway but little is known about the mechanisms by which cannabinoids regulate osteoclast activity. There have been major discrepancies between different studies with regard to the effects of different cannabinoid receptor ligands on osteoclast differentiation and function. These remain to be completely resolved but some of the discrepancies between studies could be due to the fact that many cannabinoid receptor ligands which were previously thought to be specific for CB1 and/or CB2 have now been shown to have effects on GPR55 signaling (Kapur et al., 2009;
will greatly enhance our understanding of the role of the skeletal endocannabinoid system in bone remodeling and encourage the development of new treatments for bone diseases based on targeting cannabinoid receptors.

Checa, A., Aranaz, M., Nicolussi, S., and Pertwee, R. (2009). A further area of research which remains to be explored is to determine to what extent the CB1 receptor exerts its effects on the skeleton by a central (neuronal) or peripheral mechanism. This is clinically relevant since if the peripheral effects were predominant, it may be possible to develop agonists of CB1 that do not cross the blood brain barrier, that would influence bone formation without causing adverse psychotropic effects. The outcome of these studies will greatly enhance our understanding of the role of the skeletal endocannabinoid system in bone remodeling and encourage the development of new treatments for bone diseases based on targeting cannabinoid receptors.
