Disorders of plasma sodium are the most common electrolyte disturbances in clinical medicine, yet they remain poorly understood. Severe hyponatraemia and hypernatraemia are associated with considerable morbidity and mortality, however, and even mild hyponatraemia is associated with worse outcomes when it complicates conditions such as heart failure, although which is cause and which effect is often uncertain. Distinguishing the cause(s) of hyponatraemia may be challenging in clinical practice, and controversies surrounding its management remain. Here, we describe the common causes of disorders of plasma sodium, offer guides to their investigation and management, and highlight areas of recent advance and of uncertainty.

Control of sodium balance

Under normal conditions, plasma sodium concentrations are finely maintained within the narrow range of 135-145 mmol/l despite great variations in water and salt intake. Sodium and its accompanying anions, principally chloride and bicarbonate, account for 80% of the extracellular fluid osmolality, which is normally 285-295 mosm/kg and calculated as (2× [Na+]mmol/l + [urea]mmol/l + [glucose]mmol/l). The main determinant of the plasma sodium concentration is the plasma water content, itself determined by water intake (thirst or habit), “insensible” losses (such as metabolic water, sweat), and urinary dilution. The last of these is under most circumstances the most important and is predominantly determined by arginine vasopressin, which is synthesised in the hypothalamus and then stored in and released from the posterior pituitary. In response to arginine vasopressin, concentrated urine is produced by water reabsorption across the renal collecting ducts. This is mediated by specialised cellular membrane transport proteins called aquaporins.

Hyponatraemia

Determining the cause of hyponatraemia may be straightforward if an obvious precipitating cause is present—for example, in the setting of vomiting or diarrhoea, when both sodium and total body water are low, and especially if the patient (typically elderly) is taking diuretics. In hospital practice, diagnosing the cause is often less clear cut. Here, hyponatraemia almost always reflects an excess of water relative to sodium, commonly by dilution of total body sodium secondary to increases in total body water (water overload) and sometimes as a result of depletion of total body sodium in excess of concurrent body water losses. The clinical classification of hyponatraemia according to the patient’s extracellular fluid volume status, as hypovolaemic, euvoalaemic, or hypervolaemic (box 1), is useful to help with the diagnosis. In practice, however, distinguishing euvoalaemic and hypervolaemic hyponatraemia may not be straightforward.

The symptoms of hyponatraemia are related to both the severity and the rapidity of the fall in the plasma sodium concentration and include headache, nausea, vomiting, seizures, and coma. The symptoms are related to the fall in ionic sodium and therefore the increase in osmolality of extracellular fluid. In addition, although the symptoms are often attributed to increased extracellular fluid volume, this is usually not the case and is to be avoided, especially in elderly patients with reduced intravascular volume. The symptoms are ameliorated by correction of the hyponatraemia at a rate that is relatively slow and safe (see box).
sodium concentration. A decrease in plasma sodium concentration creates an osmotic gradient between extracellular and intracellular fluid in brain cells, causing movement of water into cells, increasing intracellular volume, and resulting in tissue oedema, raised intracranial pressure, and neurological symptoms. Patients with mild hyponatraemia (plasma sodium 130-135 mmol/l) are usually asymptomatic. Nausea and malaise are typically seen when plasma sodium concentration falls below 125-130 mmol/l. Headache, lethargy, restlessness, and disorientation follow, as the sodium concentration falls below 115-120 mmol/l. With severe and rapidly evolving hyponatraemia, seizure, coma, permanent brain damage, respiratory arrest, brain stem herniation, and death may occur. In more gradually evolving hyponatraemia, the brain self regulates to prevent swelling over hours to days by transport of, firstly, sodium, chloride, and potassium and, later, organic solutes including glutamate, taurine, myo-inositol, and glutamine from intracellular to extracellular compartments. This induces water loss and ameliorates brain swelling, and hence leads to few symptoms in patients with chronic hyponatraemia.

**History, examination, and investigation**

An accurate history may reveal a clue to the cause of the hyponatraemia and establish the rapidity of the symptoms. The key diagnostic factors (box 2) are the hydration status of the patient and the urine “spot sodium” concentration, which is available quickly and allows the crucial distinction in hypovolaemic hyponatraemia between renal (high; >30 mmol/l) and extrarenal (low; <30 mmol/l) salt loss. Urinary sodium is similarly helpful in patients in whom volume status is difficult to assess, as patients with dilutional hyponatraemia by and large have a urinary sodium >30 mmol/l, whereas those with extracellular fluid depletion (unless the source is renal) will have a urinary sodium <30 mmol/l. Plasma osmolality is almost always low in hyponatraemia, and urine is less than maximally dilute (inappropriately concentrated); so, although usually measured, plasma and urine osmolalities are rarely discriminant.

**Box 1: Classification of hyponatraemia**

**Hypovolaemia**

- Renal loss, urine sodium >30 mmol/l
  - Diuretics
  - Salt wasting nephropathy
  - Cerebral salt wasting
  - Mineralocorticoid deficiency (Addison’s disease)

**Euvolaemia**

- Urine sodium <30 mmol/l, but may be >30 if dietary access to salt restricted
- Most difficulty arises in differentiating mild hypovolaemia from euvolaemic, dilutional, hyponatraemia. In both hypovolaemic and euvolaemic hyponatraemia, plasma osmolality will be low and the urine will be less than maximally dilute (inappropriately concentrated). Plasma osmolality/urine osmolality will rarely help clinical management

**Hyponatraemia**

- Syndrome of inappropriate antidiuretic hormone secretion (SIADH)†
- Hypothyroidism
- Hypopituitarism (glucocorticoid deficiency)
- Water intoxication:
  - Primary polydipsia
  - Excessive administration of parenteral hypotonic fluids
- Post-transurethral prostatectomy

*Paradoxical retention of sodium and water despite a total body excess of each; baroreceptors in the arterial circulation perceive hypoperfusion, triggering an increase in arginine vasopressin release and net water retention.

†Remember that SIADH is a diagnosis of exclusion.

**Management of hyponatraemia**

As the duration of hyponatraemia may be difficult to judge, the presence of symptoms and their severity should guide the treatment strategy (figure). Acute hyponatraemia developing within 48 hours carries a risk of cerebral oedema, so prompt treatment is indicated with apparently small risk of central pontine myelinoly-

Clinical review

Box 2: Examination and investigations in patient with hyponatraemia

**Evaluation of volume status**
- Skin turgor
- Pulse rate
- Postural blood pressure
- Jugular venous pressure
- Consider central venous pressure monitoring
- Examination of fluid balance charts

**General examination for underlying illness**
- Congestive cardiac failure
- Cirrhosis
- Nephrotic syndrome
- Addison’s disease
- Hypopituitarism
- Hypothyroidism

**Investigations**
- Urinary sodium
- Plasma glucose and lipids
- Renal function
- Thyroid function
- Peak cortisol during short synacthen test†
- Plasma and urine osmolality‡
- If indicated: chest x-ray, and computed tomography and magnetic resonance imaging of head and thorax

*Pseudohyponatraemia due to artefactual reduction in plasma sodium in the presence of marked elevation of plasma lipids or proteins should no longer be seen with the measurement of sodium by ion specific electrodes; hyperglycaemia causes true hyponatraemia, irrespective of laboratory method.
†May be unhelpful in pituitary apoplexy, in which patients may still “pass” the test.
‡For SIADH: plasma osmolality < 270 mosm/kg with inappropriate urinary concentration (> 100 mosm/kg), in a euvoalaemic patient after exclusion of hypothyroidism and glucocorticoid deficiency.

Hyponatraemia

Hyponatraemia is much less common than hypernatraemia. It reflects a net water loss or a hypertonc
sodium gain, with inevitable hyperosmolality. Severe symptoms are usually evident only with acute and large increases in plasma sodium concentrations to above 158-160 mmol/L. Importantly, the sensation of intense thirst that protects against severe hypernatraemia in health may be absent or reduced in patients with altered mental status or with hypothalamic lesions affecting their sense of thirst (adipsia) and in infants and elderly people. Non-specific symptoms such as anorexia, muscle weakness, restlessness, nausea, and vomiting tend to occur early. More serious signs follow, with altered mental status, lethargy, irritability, stupor, or coma. Acute brain shrinkage can induce vascular rupture, with cerebral bleeding and subarachnoid haemorrhage.

History, examination, and investigation
Often the cause is evident from the history (Box 3). Measurement of urine osmolality in relation to the plasma osmolality and the urine sodium concentration help if the cause is unclear. Patients with diabetes insipidus present with polyuria and polydipsia and lower urinary osmolality. Central diabetes insipidus insipidus may be related to a disturbance of thirst, which appears to be impaired in diabetes insipidus. Treatment of nephrogenic diabetes insipidus is often related to the response to water deprivation (failure to concentrate urine) followed by the V2 agonist desmopressin, causing concentration of urine in patients with central diabetes insipidus.

Management
In patients with hypernatraemia that has developed over a period of hours, rapid correction of plasma sodium (falling by 1 mmol/L per hour) improves the prognosis without the risk of convulsions and cerebral oedema. Management of a shocked patient needs specialist input and close monitoring, preferably in a high dependency unit. Intravenous normal saline should be used to correct the extracellular fluid deple- tion, with calculation of the free water deficit to determine how much 5% dextrose to give. In patients with hypernatraemia of longer or unknown duration, reducing the sodium concentration more slowly is prudent. Patients should be given intravenous 5% dextrose for acute hypernatraemia or half-normal saline (0.45% sodium chloride) for chronic hypernatraemia if unable to tolerate oral water. Central diabetes insipidus is treated with desmopressin, either as intranasal spray or tablets, with careful monitoring to avoid the complications of water intoxication (delaying one dose each week to allow polyuria and thirst to “breakthrough” in patients susceptible to hyponatraemia with desmopressin may be prudent). Treatment of nephrogenic diabetes insipidus insipidus may be differentiated by the response to water deprivation (failure to concentrate urine) followed by the V2 agonist desmopressin, causing concentration of urine in patients with central diabetes insipidus.

Final thoughts
Despite the frequent occurrence and the poor outcomes of serious disorders of sodium balance, few hard data are available to guide the clinician. This area needs clinical trials, notably of existing approaches (water restriction, demeclocyline, rates of dehydration and rehydration), to complement industrially funded randomised controlled trials of novel aquaretics.

Box 3: Classification of hypernatraemia

**Hypovolaemia**
- Dermal losses—for example, burns, sweating
- Gastrointestinal losses—for example, vomiting, diarrhoea, fistulas

**Diuretics**
- Postobstruction
- Acute and chronic renal disease
- Hypersomolar non-ketotic coma

**Hypervolaemia**
- Iatrogenic (hypertonic saline, tube feedings, antibiotics containing sodium, or hypertonic dialysis)
- Hyperaldosteronism†

**Euuvolaemia**
- Diabetes insipidus (central, nephrogenic, or gestational)
- Hypodipsia
- Fever
- Hyperventilation
- Mechanical ventilation

*Sodium often raised, even after correction for glucose
†Typically mildly elevated sodium ~ 147 mmol/L, so rarely a clinical problem
