Omega 3 fatty acids and cardiovascular disease—fishing for a natural treatment

Omega 3 fatty acids from fish and fish oils can protect against coronary heart disease. This article reviews the evidence regarding fish oils and coronary disease and outlines the mechanisms through which fish oils might confer cardiac benefits.

Several areas of uncertainty remain. The optimal intake of omega 3 fatty acids is not firmly established, nor is their mechanism of action fully understood. Some studies have produced conflicting results, and concerns have been increasing about environmental contamination of certain fish. This article reviews the current evidence regarding fish oils and cardiovascular disease, their possible mechanism of action, and potential future developments and research strategies.

Sources and selection criteria

We searched PubMed for relevant articles by using the key words “fish,” “fish oils,” “omega 3 fatty acids,” and “cardiovascular disease.” References identified in the search are on bmj.com

Summary points

Coronary heart disease is still the most common cause of death in the United Kingdom

Omega 3 fatty acids from fish and fish oils can protect against coronary heart disease

There is evidence to support the use of fish or fish oil supplements after myocardial infarction

The mechanisms by which fish oils confer their benefits are not fully understood

Unravelling these mechanisms may identify novel therapeutic targets and could help guide the development of future treatments for coronary heart disease

Future trials may identify other patients who could benefit, such as those with stable angina, risk factors for coronary heart disease, or left ventricular dysfunction

Omega 3 polyunsaturated fatty acids

The association between omega 3 fatty acids and cardiovascular disease was established following the observation that the Greenland Inuit had low mortality from coronary heart disease despite a diet that is rich in fat. In the 1970s the Danish investigators Bang and Dyerberg proposed that this could be because of the high content of omega 3 fatty acid in the Inuit diet,1 which consisted largely of fish, seal, and whale (fig 1).

Omega-3 fatty acids

Omega-3 fatty acids, along with omega-6 fatty acids, are essential polyunsaturated fatty acids (fig 2 and fig 3). The Western diet is abundant in omega-6 fatty acids, mainly from vegetable oils rich in linoleic acid. However, humans lack the necessary enzymes to convert omega-6 fatty acids to omega-3 fatty acids, and the latter must be obtained from separate dietary sources. While α-linolenic acid is available from certain plants, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are derived from fish and fish oils. This review is limited to the two marine derived omega-3 fatty acids.

The investigators speculated that this may have arisen from risk compensation or other changes in patients’ behaviour. Several flaws in this study weakened the validity of the results, and they should be viewed with caution until more evidence becomes available.

Clinical intervention trials

Several trials have assessed the effects of fish and fish oil supplements on coronary heart disease, mainly after myocardial infarction (table 1). The diet and reinfarction trial (DART) randomised 2035 men with a recent myocardial infarction to three dietary interventions. Patients who received advice on fish had a relative reduction in total mortality of 29% during the two year follow up (P < 0.05), mainly because of a reduction in deaths from coronary heart disease. The open label Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto Miocardico Prevenzione (GISSI-Prevenzione) trial randomised 11 324 patients after myocardial infarction to either a daily capsule of about 850 mg omega-3 fatty acid, 300 mg vitamin E, both, or neither. After 3.5 years participants randomised to fish oil capsules had a reduction in relative risk of 15% in the composite primary end point of total mortality, non-fatal myocardial infarction, and stroke (P = 0.023).

The relative risk of cardiovascular death was also reduced, by 30% (P = 0.024), and of sudden death by 45% (P = 0.01). These benefits were apparent within just four months of randomisation.

Two smaller secondary prevention trials have also assessed the effects of omega-3 fatty acids. In an Asian population patients with a suspected myocardial infarction randomised to fish oil capsules experienced a significant reduction in mortality from coronary heart disease after one year compared with placebo. However, a Norwegian study reported no benefit in patients after myocardial infarction who were given fish oil capsules compared with placebo after 1.5 years. This may have been because of the high habitual fish consumption among the general population in that area, with omega-3 supplementation conferring no additional benefit.

A recent trial of 3114 men with angina unexpectedly found that individuals advised to eat oily fish, and particularly those given fish oil capsules, had a higher risk of cardiac death than people not given advice to eat fish (11.5% v 9%, P = 0.02). The investigators speculated that this may have arisen from risk compensation or other changes in patients’ behaviour. Several flaws in this study weakened the validity of the results, and they should be viewed with caution until more evidence becomes available.

Fig 2. Fatty acids are saturated, monounsaturated, or polyunsaturated. Two types of polyunsaturated fatty acid exist—the omega 6 and the omega 3 fatty acids. The omega 6 fatty acids are available mainly from vegetable oils. Three types of omega 3 fatty acid exist: α-linolenic acid is available from certain plants but eicosapentaenoic acid and docosahexaenoic acid must be obtained from marine sources.

Omega-3 fatty acids

Eicosapentaenoic acid: fish, shellfish
Docosahexaenoic acid: fish, shellfish
α-linolenic acid: flaxseed, soybean, walnut, rapeseed oils

Omega-6 fatty acids

Linoleic acid: vegetable oils (sunflower, corn, safflower, soybean, walnut, flaxseed)
Arachidonic acid: vegetable and animal oils (corn, safflower, soybean, walnut, flaxseed, shellfish, sunflower, palm, coconut, butter foundation of unsaturated fats.

Clinical review

Clinical intervention trials

Several trials have assessed the effects of fish and fish oil supplements on coronary heart disease, mainly after myocardial infarction (table 1). The diet and reinfarction trial (DART) randomised 2035 men with a recent myocardial infarction to three dietary interventions. Patients who received advice on fish had a relative reduction in total mortality of 29% during the two
Mechanism of action

Although the weight of evidence outlined above supports a protective effect of omega 3 fatty acids on coronary heart disease, the mechanisms through which they confer these benefits remain unclear. Omega 3 fatty acids have several potentially cardioprotective effects (box 1), although the relative contribution of each of these is not fully understood.

Arrhythmias

The benefits of fish oils were originally thought to be due to their antithrombotic effects, but recent evidence has indicated that the predominant effect may be antiarrhythmic. In the GISSI-Prevenzione trial the decrease in mortality was largely due to a reduction in sudden death,11 and, as in DART,12 no reduction in the rate of non-fatal myocardial infarction occurred. Fish oil supplementation increases heart rate variability in patients after myocardial infarction, which correlates with a lower risk of mortality and malignant arrhythmia.13 In animal models fish oil protects against ventricular fibrillation after surgical occlusion of a coronary artery.14 The addition of eicosapentanoic acid or docosahexanoic acid can prevent or terminate pharmacologically induced arrhythmias in cultured cardiomyocytes from newborn rats.15 However, studies are necessary to show a direct antiarrhythmic effect in humans and trials are currently under way in patients with implantable defibrillators.

Thrombosis

Activation of platelets and their deposition at sites of unstable plaque rupture promotes thrombus formation, and these critical events have become a common therapeutic target in acute coronary syndromes. However, the effects of omega 3 fatty acids on platelet function and thrombosis are controversial. Large doses reduce platelet aggregation, but smaller amounts have modest platelet inhibitory effects.16 Omega 3 fatty acids have inconsistent effects on fibrinolysis and little effect on blood coagulability.17 Therefore, although omega 3 fatty acids have an antithrombotic effect, its relevance to the mortality reduction seen with lower doses is unclear.

Atherosclerosis

Omega 3 fatty acids may also influence the atherosclerotic process. Fish oil fed to experimental animals protects against progression of atherosclerotic plaques.18–20 In humans with coronary heart disease omega 3 fatty acid supplementation versus placebo for two years resulted in modest improvements in atherosclerosis as assessed by angiography.21 These effects may be due to a reduction in lipids, inflammation, production of growth factor, or suppression of smooth muscle cell proliferation.22 An important recent study randomised patients awaiting carotid endarterectomy to fish oil capsules, sunflower oil capsules, or control until surgery and then assessed morphology of the plaque.23 Omega 3 fatty acids were readily incorporated into atherosclerotic plaques in the fish oil group, and these plaques were more likely to have thick fibrous caps and less inflammatory infiltrate. These features imply a plaque that is less vulnerable to rupture and indicate that fish oils may be important in establishing stability of the plaque.

Inflammation

Inflammation has a central role in the development and progression of coronary artery disease. Omega 3 fatty acids may also influence the inflammatory process.24–26 Omega 3 fatty acids have several potentially cardioprotective effects (box 1), although the relative contribution of each of these is not fully understood.

Table 1: Possible mechanisms of action of omega 3 fatty acids

- Antiarrhythmic
- Antithrombotic
- Antinflammatory
- Antiatherosclerotic
- Improves endothelial function
- Lowers blood pressure
- Lowers triglyceride concentrations
fatty acids have recognised anti-inflammatory actions that may contribute to their beneficial cardiac effects. Omega 6 fatty acids can be converted into arachidonic acid and then metabolised into the omega 6 eicosanoids (fig 4). These cellular mediators enhance platelet aggregation and are generally pro-inflammatory. Consumption of omega 3 fatty acids increases eicosapentanoic acid in the cell membrane. This competes with arachidonic acid for enzymatic conversion into its own metabolites, the omega 3 derived eicosanoids. These are less active and can partly oppose or antagonise the pro-inflammatory actions of the omega 6 eicosanoids.

Independent of the effects on the metabolism of eicosanoids fish oils suppress pro-inflammatory cytokines and reduce expression of cell adhesion molecules. These are critical in recruiting circulating leucocytes to the vascular endothelium, an important event in the pathogenesis of atherosclerosis and inflammation. These effects may be mediated through actions on intracellular signalling pathways, leading to reduced activation of transcription factors such as NF-kB. However, the precise effects of omega 3 fatty acids on these fundamental cellular processes and their potential impact on coronary heart disease are yet to be delineated completely.

**Endothelial function**
Abnormal endothelial function is found in individuals with cardiovascular risk factors or established coronary heart disease. Omega 3 fatty acids have direct effects on endothelial vasomotor function. Higher concentrations are associated with improved dilation of the brachial artery in young adults with cardiovascular risk factors, which implies a protective effect on endothelial function.

**Blood pressure**
Fish oils can produce modest reductions in blood pressure, possibly through their effects on endothelial function discussed above. A recent meta-analysis of 36 randomised trials found a reduction in systolic blood pressure of 2.1 mm Hg and in diastolic blood pressure of 1.6 mm Hg. However, most trials used relatively high doses of fish oils (3.6 g/day), and the effects of lower intakes of omega 3 fatty acids, such as those in the secondary prevention trials, remain to be established.

**Triglyceride lowering**
Omega 3 fatty acids reduce triglyceride concentrations in a dose dependent manner, with intakes of about 4 g per day lowering serum triglycerides by 25-30%. Their effect on cholesterol is small and of uncertain clinical importance. Higher doses (3-5 g/day) can be used in the treatment of hypertriglyceri-

---

**Box 2: Recommendations for intake of omega 3 fatty acids**
- Patients without documented coronary heart disease: Eat a variety of (preferably oily) fish at least twice weekly. Include oils and foods rich in α-linolenic acid
- Patients with documented coronary heart disease: Consume 1 g of eicosapentanoic and docosahexanoic acid daily, preferably from oily fish. Supplements could be considered in consultation with a doctor
- Patients with hypertriglyceridaemia: Take 2-4 g of eicosapentanoic acid and docosahexanoic acid daily, provided as capsules under a doctor’s care

These are the recommendations of the American Heart Association.

---

**Box 3: Consumption and sources of marine derived omega 3 fatty acids**
- Current consumption of marine derived omega 3 fatty acids is low, at 0.1-0.2 g/day. An expert US panel of nutrition scientists has recommended an intake of 0.05 g/day whereas the British Nutrition Foundation’s recommendation is 1.2 g/day. Secondary prevention trials after myocardial infarction indicate that consumption of 0.5-1.8 g/day of eicosapentanoic and docosahexanoic acid from fish or fish oil supplements may be beneficial. Intake of marine derived omega 3 fatty acids can be increased through diet or with fish oil supplements. Oily fish such as mackerel, herring, tuna, salmon, sardines and trout are rich sources of eicosapentanoic and docosahexanoic acid (table 2), and two to three servings per week should provide approximately 1 g/day omega 3 fatty acids. Lean fish such as cod or haddock have smaller amounts, and fried fish (for example, from fast food establishments or frozen products) contains minimal amounts of omega 3 fatty acids.
- Concerns about the depletion of fish stocks will become more pressing if the benefits of fish oils are confirmed beyond the population after myocardial infarction, as this may result in an unsustainable increase in demand. Alternative strategies to increase omega 3 intake include supplementing animal feed with fish oil to augment the omega 3 content of eggs, meat, and milk. Available foods can also be enriched in eicosapentanoic and docosahexanoic acid, although they may impart a fishy aroma or flavour. A different approach independent of an adequate supply of fish oil would involve using modern biotechnology to genetically modify certain plants species, thereby producing plants and plant oils rich in eicosapentanoic and docosahexanoic acid.

EPA=eicosapentanoic acid, DHA=docosahexanoic acid.

Omega 3 content varies markedly depending on species, season, diet, and packaging and cooking methods, and the figures above are therefore rough estimates.

daemia. Only a small reduction in triglycerides occurred at the lower doses used in the GISSI-Prevenzione trial[23] (about 1 g/day), and it therefore seems unlikely that this effect alone could be responsible for the cardiovascular benefits.

Clinical implications

Omega 3 fatty acids from fish or fish oil supplements should be considered in the secondary prevention regi-
capsules also require further investigation. In addition to trials with clinical end points, research efforts should be focused on understanding the mechanisms by which fish oils might confer cardiac benefits. This will allow us not only to refine the clinical applications of ADFs but hopefully also to identify other therapeutic targets and help guide the development of future treatments for coronary heart disease.

Corrections and clarifications

Editor’s Choice and the filler “An extreme failure of concordance”

In his Editor’s Choice of 11 October, Richard Smith wrote about the failure of communication between a Hmong family in California with a daughter with severe epilepsy and the California healthcare system—as described in a book from which we published an extract in the same issue (as a “filler,” p 857). Unfortunately, Smith said that Liu had now died. He was wrong to say this; she is still alive. Anne Fadiman, the author of the book (The Spirit Catches You and You Fall Down) has asked us to make clear that “Liao suffered profound neurological damage after an episode of status epilepticus and that the parents thought that the doctors and their drugs had injured her rather than helped.” In the filler, we also misspelt the first name of the book’s author and introduced a rogue apostrophe into the word “fractions.” We apologise for these errors to all concerned.

Communicating risks at the population level: application of population attributable risk numbers

Richard F Heller and colleagues have reported an error in their Education and Debate article (15 November, pp 1162-5) that was due to a little recognised problem in calculating population attributable risk for multiple levels of exposure. This led to an overestimation of population attributable risk in table 2, which shows the impact of blood cholesterol concentration on premature death from coronary heart disease (p 1164). However, this does not alter the general conclusion drawn from the table (that the population impact of cholesterol concentrations of 2.6-5.5 mmol/l and of 6.5-7.8 mmol/l is larger than that of concentrations above 7.8 mmol/l or the substance of the article. Full details of the correct calculations and the corrected table 2 appear on bmj.com (http://bmj.bmjournals.com/cgi/content/full/327/7424/1162/DC1).
