ABSTRACT

There is empirical evidence that genotypes differ not only in mean, but also in environmental variance of the traits they affect. Genetic heterogeneity of environmental variance may indicate genetic differences in environmental sensitivity. The aim of this study was to develop a general framework for prediction of breeding values and selection responses in mean and environmental variance with genetic heterogeneity of environmental variance. Both means and environmental variances were treated as heritable traits. Breeding values and selection responses were predicted with little bias using linear, quadratic, and cubic regression on individual phenotype or using linear regression on the mean and within-family variance of a group of relatives. A measure of heritability was proposed for environmental variance to standardize results in the literature and to facilitate comparisons to “conventional” traits. Genetic heterogeneity of environmental variance can be considered as a trait with a low heritability. Although a large amount of information is necessary to accurately estimate breeding values for environmental variance, response in environmental variance can be substantial, even with mass selection. The methods developed allow use of the well-known selection index framework to evaluate breeding strategies and effects of natural selection that simultaneously change the mean and the variance.

The standard genetic model in quantitative genetics is that phenotype $P$ is the sum of genotype $G$ and environment $E$: $P = G + E$ (Falconer and Mackay 1996). The phenotypic variance can be written as $\sigma_P^2 = \sigma_G^2 + \sigma_E^2$, assuming no covariance between $G$ and $E$. This model allows for genetic differences in mean ($G$), with a genetic variance $\sigma_G^2$. For different genotypes, environmental variances ($\sigma_E^2$) are assumed to be constant. On the basis of analysis of field data and laboratory (selection) experiments, there is, however, some empirical evidence that genotypes differ in $\sigma_E^2$.

Several studies have been carried out to quantify genetic differences in environmental variance in field data. SanCristobal-Gaudy et al. (2001), Sorensen and Waagepetersen (2003), and Ros et al. (2004) explicitly modeled genetic differences in environmental variance and found substantial genetic variance in environmental variance for litter size in sheep, litter size in pigs, and body weight in snails, respectively. Van Vleck (1968) and Clay et al. (1979), in analysis of milk yield in dairy cattle, and Rowe et al. (2006), in analysis of body weight in broiler chickens, found large differences between sires in phenotypic variance within progeny groups. In these studies, it was not possible to distinguish whether these differences were due to heterogeneity of environmental variance, genetic variance, or both.

Several selection experiments have been carried out to investigate whether phenotypic variance can be changed by selection. Phenotypic variance changed in some selection experiments with Drosophila melanogaster and Tribolium castaneum (Rendel et al. 1966; Kaufman et al. 1977; Cardin and Minvielle 1986), while it did not in an experiment with mice (Falconer and Robertson 1956). In these experiments, it was not always clear whether the response in variance was due to a change in environmental variance, genetic variance, or both.

Mackay and Lyman (2005) derived 300 isofemale lines of Drosophila and computed the coefficient of variation (CV) for environmental variance within each homozygous line, effectively a clone, and within crosses of each line with another inbred line. They found highly significant genetic variance in the CV and in environmental variance between lines. Homozygotes had higher environmental variance, in agreement with findings of Robertson and Reeve (1952). This study is probably the cleanest known example of showing genetic variance in environmental variance because the design allowed repetition of genotypes.

In livestock and plant breeding, uniformity of end product is an important topic. In meat type animals, for
instance, uniformity has economic benefits because excessive variability in carcass weight or conformation is penalized by slaughterhouses. Hoheboken (1985) reviewed the potential of mating systems (crossing, inbreeding) and breeding schemes to change variability. To evaluate breeding strategies, methods to predict responses to selection for uniformity are necessary. Sanristobal-Gaudy et al. (1998) derived prediction equations and Sanristobal-Gaudy et al. (2001) evaluated different selection indices using Monte Carlo simulation when the aim was to select for an optimum phenotype and thereby decrease the variance around the optimum (canalizing selection). Sorensen and Waagepetersen (2003) evaluated response to selection using an index including the mean and the variance of multiple records of an individual and Ros et al. (2004) discussed the use of a restricted index aiming at decreasing the environmental variance, while maintaining the mean. Hill and Zhang (2004) derived simple equations to predict response to directional mass selection with genetic heterogeneity of environmental variance. In general, these prediction equations can be used only in special cases. A general framework to predict responses in mean and variance is lacking.

The objective of the present study was to develop a general framework for prediction of breeding values and responses to selection with genetic heterogeneity of environmental variance. Responses to selection were predicted for different forms of selection based on a single phenotype, as well as selection on a mean or variance of a group of relatives. Furthermore, a measure of heritability of environmental variance was developed, enabling a direct comparison between selection to change the environmental variance of a trait and the well-established framework of selection to change its mean.

DERIVATION AND EVALUATION OF EXPRESSIONS

In this section, the model incorporating genetic heterogeneity of environmental variance is defined and the framework for prediction is explained. Prediction of breeding values and selection responses based on a single phenotype and a group of relatives are then considered, in each case using Monte Carlo simulation to investigate the relationships between true breeding values and phenotypic information. Using these observations, multiple-regression equations are derived for one generation of selection and their goodness of fit is evaluated by simulation. Finally, a measure of heritability for environmental variance is proposed.

Genetic model and framework for prediction

The classical model, in the absence of dominance and epistasis, \( P = A + E \) (Falconer and Mackay 1996), is extended to include an additive genetic effect for the environmental variance,

\[
P = \mu + A_m + \chi \sqrt{\sigma_E^2 + A_v}
\]

(Hill and Zhang 2004), where \( \mu \) and \( \sigma_E^2 \) are, respectively, the mean trait value and the mean environmental variance of the population, \( A_m \) and \( A_v \) are, respectively, the breeding value for the mean and environmental variance, and \( \chi \) is a standard normal deviate for the environmental effect. It is assumed that \( A_m \) and \( A_v \) are the sum of the effects at an infinite number of loci each with small additive effects and follow a multivariate normal distribution \( N\left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \mathbf{C} \otimes \mathbf{A}\right) \), where \( \mathbf{A} \) is the additive genetic relationship matrix,

\[
\mathbf{C} = \begin{bmatrix}
\sigma_A^2 & \text{cov}_{AV} \\
\text{cov}_{AV} & \sigma_V^2
\end{bmatrix}
\]

\( \sigma_A^2 \) is the additive genetic variance in \( A_m \), \( \sigma_V^2 \) is the additive genetic variance in \( A_v \), \( \text{cov}_{AV} = \text{cov}(A_m, A_v) = r(A_m, \sigma_{A_v}, r_v \sigma_A^2, \text{ and } r_A \) is the additive genetic correlation between \( A_m \) and \( A_v \). The term \( \chi \) is normally distributed \( N(0,1) \) and is scaled by \( \sqrt{\sigma_E^2 + A_v} \) to obtain the environmental effect. The notation is listed in Table 1.

The genetic model in Equation 1 does not allow for random environmental effects on the magnitude of the environmental variance, because without repeated measurements on each individual these cannot be separated from the usual random environmental effects. With repeated measurements on each individual, these environmental effects on environmental variance become equivalent to permanent environmental effects (e.g., Sanristobal-Gaudy et al. 1998; Sorensen and Waagepetersen 2003).

To predict the breeding values \( \hat{A}_m \) and \( \hat{A}_v \) and selection responses \( \Delta A_m \) and \( \Delta A_v \), multiple regression was used. Selection index theory is essentially an application of multiple regression (Hazel 1943). Multiple regression gives the best linear prediction (BLP), which is equal to best linear unbiased prediction (BLUP) when fixed effects are known without error (Henderson 1984). When variables are multivariate normally distributed, regressions are linear and homoscedastic (Lynch and Walsh 1998). Although the distribution of \( P \) deviates slightly from normality with genetic heterogeneity of environmental variance (\( \sigma_A^2 > 0 \)), \( P, A_m, \) and \( A_v \) follow an approximately multivariate normal distribution for values of \( \sigma_A^2 \) observed in the literature (e.g., Sanristobal-Gaudy et al. 2001; Sorensen and Waagepetersen 2003; Ros et al. 2004; Rowe et al. 2006), justifying the use of multiple regression.

Multiple regression with selection on a single phenotype

Monte Carlo simulation: Monte Carlo simulation was used to investigate the relationships between \( A_m \) and \( A_v \),

with $P$, with the objective to decide which order of fit would be required for accurate prediction and then to evaluate the fit of predictions on the basis of multiple regressions. Fifty replicates with one phenotypic observation on each of 500,000 unrelated animals in each replicate were generated according to the genetic model in Equation 1, assuming $\mu = 0$. The breeding values $A_m$ and $A_v$ and the environmental effect $\chi$ were randomly drawn from $N(0,1)$ and scaled by their corresponding standard deviations. When the genetic correlation between $A_m$ and $A_v$ was nonzero, $A_v$ was sampled given the expected value based on $A_m$ with variance $(1-r_{A_m,A_v})\sigma^2_{A_m}$. Expected breeding values were calculated as the mean $A_m$ and $A_v$ within successive intervals of 0.01 units of $P$ ($\sigma^2_P = 1$) and averaged over replicates. Expected selection responses to directional mass selection were calculated as the mean $A_m$ and $A_v$ of all selected animals having $P \geq x$ and averaged over replicates, where $x$ is the truncation point. The selected proportion was assumed to be the same in both sexes.

**Breeding value estimation:** Figure 1, A and B, presents, respectively, the expectation of $A_m$ given $P$ and the expectation of $A_v$ given $P^2$ when $r_{A_m} = 0$, obtained by simulation. These show that the relationship between $A_m$ and $P$ is almost linear and that the relationship between $A_v$ and $P^2$ is also almost linear (quadratic in $P$). Therefore, $P - \mu$ roughly predicts $A_m$ and regression on $[P - \mu]^2 - E\{[P - \mu]^2\}$ roughly predicts $A_v$. As a consequence of genetic heterogeneity of environmental variance, the distribution of $P$ is slightly leptokurtic and is slightly skewed when $r_{A_m} \neq 0$. By fitting curves to the simulation results, it was found that regression on $[P - \mu]^3 - E\{[P - \mu]^3\}$ explained most of the residual nonlinearity and skewness when $r_{A_m} \neq 0$. Moments of $P$ of higher order did not improve the fit and were therefore not considered in the rest of this study.

On the basis of this curve fitting, breeding values were predicted using multiple regression on the first through third order of $P$,

$$\hat{a} = B \cdot x,$$

where

$$a = \begin{bmatrix} A_m \\ A_v \end{bmatrix} \quad x = \begin{bmatrix} P - \mu \\ [P - \mu]^2 - E\{[P - \mu]^2\} \end{bmatrix} \quad \frac{P}{P^2 - \sigma^2_p} \quad \frac{P^3 - 3 \text{cov}_{A_m}}{\mu = 0}.$$

$$B = P^{-1}G,$$

$$P = \text{cov}(x,x) = \begin{bmatrix} \sigma^2_p & 3 \text{cov}_{A_m} & 3\sigma^2_v + 3\sigma^2_A \\ 3 \text{cov}_{A_m} & 2\sigma^2_v + 3\sigma^2_A \\ 3\sigma^2_v + 3\sigma^2_A & 27\text{cov}_{A_m} & 15\sigma^2_v + 45\sigma^2_A \end{bmatrix},$$

and

$$G = \text{cov}(x,a) = \begin{bmatrix} \sigma^2_{A_m} & \text{cov}_{A_m} & \sigma^2_v \\ \sigma^2_{A_m} & \sigma^2_v & 3\sigma^2_A \\ 3\sigma^2_v & 3\sigma^2_A & 3\sigma^2_{A_m} \end{bmatrix}.$$
Evaluation of predictions: Predictions of Equation 2 were close to the expectations obtained from Monte Carlo simulation when \( r_A = 0 \), as could be expected from the almost linear relationships shown in Figure 1, A and B (\( R^2 > 0.98 \)). For \( r_A = 0.5 \), Figure 2A shows that \( A_m \) is approximately linear in \( P \) with a slope close to \( h_m^2 = \sigma^2_{A_m}/\left(\sigma^2_{A_m} + \sigma^2_E\right) = 0.3 \), for \( P \) within two standard deviations (SD) of its mean, but becomes curvilinear for extreme \( P \). The predicted \( A_m \) using the full model with multiple regressions on \( P, P^2, \) and \( P^3 \) fitted well to the expectations obtained from Monte Carlo simulation (\( R^2 > 0.99 \)) and, in contrast to multiple regressions on only \( P \) and \( P^2 \), also explained the nonlinearity in the extremes.

Figure 2B shows that the relationship between \( A_v \) and \( P \) is highly curvilinear for \( r_A = 0.5 \), with higher \( A_v \) for more extreme \( P \). As for \( A_m \), the predicted \( A_v \) using the full model with multiple regressions on \( P, P^2, \) and \( P^3 \) fitted well to the expectation from Monte Carlo simulation (\( R^2 > 0.99 \)). The use of only \( P \) and \( P^2 \) was adequate only within 2 SD of the mean, but was biased for extreme \( P \).

Response to mass selection: Response to selection (\( \Delta G \)) is predicted as \( \Delta G = bS \), where \( b \) is the regression coefficient of the breeding value on the selection criterion, and \( S \) is the selection differential in units of the selection criterion (e.g., phenotype) (Falconer and Mackay 1996). With homogenous environmental variance and directional mass selection, \( b = h^2 \) and \( S = \sigma^2_P \), where \( i \) is the selection intensity, and \( \Delta G = \partial h^2_m \sigma_P \) is the breeders’ equation (Falconer and Mackay 1996; Lynch and Walsh 1998). With genetic heterogeneity of environmental variance, directional mass selection leads to responses in mean and variance (Hill and Zhang 2004). To predict this, Equation 2 can be rewritten as \( \Delta a = B'\Delta x \), giving

\[
\begin{bmatrix}
\Delta A_m \\
\Delta A_v
\end{bmatrix} = B' \begin{bmatrix}
\bar{P}_m \\
\bar{P}_v
\end{bmatrix} - \begin{bmatrix}
\bar{P}_m^2 - \sigma^2_P \\
\bar{P}_v^2 - 3 \text{cov}_{A_m}
\end{bmatrix}_{\mu=0}
\]

(3)

where \( \bar{P}_m, \bar{P}_v, \) and \( \bar{P}_s \) are the respective means for the selected animals.

Directional selection: With directional selection by truncation, \( \bar{P}_s = i \sigma_P \), where \( i = \frac{z}{p} \) for normally distributed observations, \( z \) is the height of the standardized normal at the truncation point \( x \), and \( p \) is the selected proportion (Falconer and Mackay 1996; Lynch and Walsh 1998). \( \bar{P}_m^2 \) and \( \bar{P}_v^2 \) were calculated by integration assuming that \( P \) is normally distributed, which is approximately the case for observed values of \( \sigma^2_P \) in the literature:

\[
\bar{P}_m^2 = (ix + 1)\sigma^2_P \tag{4a}
\]

\[
\bar{P}_v^2 = (ix^2 + 2i)\sigma^2_P \tag{4b}
\]
The predicted response to directional mass selection is thus

\[
\begin{bmatrix}
\Delta A_m \\
\Delta A_v
\end{bmatrix} = B \begin{bmatrix}
\frac{i \sigma_p}{D} \\
\frac{(ix^2 + 2)i \sigma_p}{D} \\
\end{bmatrix},
\] (5)

The term \( \overline{P^2} - \sigma_d^2 = i x \sigma_d^2 \) is similar to the term \( \frac{1}{2} i x \sigma_d^2 \) derived by Hill and Zhang (2004), who calculated the probability of selection by using a Taylor series approximation, where the factor \( \frac{1}{2} \) appears here in the \( B \)-matrix, assuming that \( r_A = 0 \) and \( \sigma_d^2 \) is small. Equation 5 can be rewritten using the regression coefficients in \( B \) and ignoring the terms involving \( P^2 \), which were not included by Hill and Zhang (2004),

\[
\Delta A_m = \frac{\sigma_A^2 (2 \sigma_P^2 + 3 \sigma_A^2) - 3 \sigma_A^2}{D} i \sigma_P + \frac{\sigma_A^2 - 3 \sigma_A^2 \text{COV} \sigma_m}{D} i \sigma_P, \quad (6)
\]

\[
\Delta A_v = \frac{2 \sigma_A^2 \text{COV} \sigma_m}{D} i \sigma_P + \frac{\sigma_A^2 - 3 \sigma_A^2 \text{COV} \sigma_m}{D} i \sigma_P, \quad (7)
\]

where \( D = \det(P) = \sigma_P^2(2 \sigma_P^2 + 3 \sigma_A^2) - 9 \sigma_A^2 \). When \( \sigma_A^2 \) and \( r_A \) are close to zero, Equations 6 and 7 approach \( \Delta A_m = (\sigma_A^2 / \sigma_d^2) i \sigma_P \) and \( \Delta A_v = (\sigma_A^2 / 2 \sigma_A^2) i \sigma_P \), which are Equations 10 and 11 of Hill and Zhang (2004). Differences arise when \( r_A \) is substantially different from zero, as the covariance between \( P \) and \( P^2 \) was ignored by Hill and Zhang.

**Stabilizing and disruptive selection:** Stabilizing and disruptive selection can be considered as selecting the animals with low or high \( P^2 \), respectively (Falconer and Mackay 1996). Assuming that selection is by truncation, selection differentials \( \overline{P^2} \) for \( P^2 \) can be obtained from Equation 4a and selection differentials for \( P \) and \( P^3 \) are zero for these types of selection when \( P \) is normally distributed. With stabilizing selection by truncation, animals only in the middle of the distribution are selected, giving a selection differential

\[
\overline{P^2} = \left[ 1 - \left( 2 \rho^* x^* / (1 - 2 \rho^*) \right) \right] \sigma_P^2, \quad (8a)
\]

where \( \rho^* \) and \( x^* \) are, respectively, the selection intensity and truncation point corresponding to \( \rho^* = \frac{1}{2} (1 - \rho) \), the proportion of animals culled on one side of the distribution. With disruptive selection by truncation, the extreme animals in both tails of the distribution are selected, giving a selection differential

\[
\overline{P^2} = (i \rho^* x^* + 1) \sigma_P^2, \quad (8b)
\]

where \( \rho^* = \frac{1}{2} \rho \), the proportion of animals selected on one side of the distribution. The standardized selection differentials \( \overline{P^2} - \sigma_d^2 \) for directional, stabilizing, and disruptive selection are in Table 2.

**Evaluation of predictions with directional mass selection:** The predictions of Equation 5 [multiple regressions (MR) 3] and Equations 6 and 7 (MR2) and those of the Hill–Zhang (HZ) model (Hill and Zhang 2004) are compared in Table 3 with the observed responses obtained from Monte Carlo (MC) simulation, for different values of \( r_A \) and selected proportions. Multiple regressions on \( P, P^2 \), and \( P^3 \) (MR3) predicted the responses well, with prediction errors <5% when the selected proportion was at least 5% (prediction error relative to \( \Delta A_m \) with \( \sigma_A^2 = 0.05 \) \( r_A = 0 \) \( \rho = 0.05 \)). Prediction errors were on average smaller for MR3 than for MR2, although occasionally larger. They were also on average slightly smaller for MR2 than for the Hill–Zhang model, especially with \( r_A = 0.5 \), because in the latter the covariance between \( P \) and \( P^2 \) was not accounted for in calculation of the regression coefficients. Prediction errors using MR were mainly due to poor prediction of selection differentials because of deviations from normality and thus increased with decreasing selected proportion as the tails of the distribution were most affected (results not shown). When \( \sigma_A^2 \) increased to 0.10 or 0.15, which reflects the upper range of estimates in the literature (e.g., San Cristobal-Gaudy et al. 2001; Ros et al. 2004), prediction errors increased up to 10–20% (prediction error relative to \( \Delta A_m \) with \( \sigma_A^2 = 0.05 \) \( r_A = 0 \) \( \rho = 0.05 \)), especially with selected proportion of 1% (results not shown). Increasing \( \sigma_A^2 \) increases deviations from normality in \( P \), but it seems that the multiple-regression framework is robust against these relatively small deviations from normality, except when the selected proportion is very small. It can be concluded that MR3 is the preferred method for predicting responses in \( A_m \) and \( A_v \) with directional mass selection,
having prediction errors <5% when at least 5% are selected.

Multiple regression with selection based on a group of relatives

Monte Carlo simulation: In animal breeding, sires are often selected on performance of their half-sib progeny. Monte Carlo simulation was used to investigate relationships between the \( A_m \) and \( A_v \) of the sires and statistics on phenotypes of their progeny and then to evaluate the fit of predictions on the basis of multiple regressions. Fifty replicates were generated of 500,000 unrelated sires each with 10 or 100 half-sib progeny or of 50,000 unrelated sires each with 1000 or 10,000 half-sib progeny. Data were simulated according to the genetic model in Equation 1. The breeding values of sires (\( A_{m,s} \) and \( A_{v,s} \)) and unrelated random-mated dams (\( A_{d,m} \) and \( A_{d,v} \)) were randomly sampled with variance \( \sigma_{A_{m}}^2 \) or \( \sigma_{A_{v}}^2 \), respectively. For each progeny, the Mendelian sampling terms \( MS_m \) and \( MS_v \) were randomly sampled with variance \( \frac{1}{2} \sigma_{A_{m}}^2 \) and \( \frac{1}{2} \sigma_{A_{v}}^2 \), respectively. For each progeny, the environmental effect \( \chi \) was randomly sampled and scaled with its standard deviation. Expected breeding values of sires were calculated as the mean \( A_m \) and \( A_v \), within successive intervals of 0.01 SD units of progeny mean \( P \) or log-transformed within-family variance [\( \ln(\text{var} W) \)] and averaged over replicates. Expected genetic selection differentials of directional selection on \( P \) were calculated as the mean \( A_m \) and \( A_v \) of all selected sires with \( \langle P/\alpha \rangle \geq x \) and averaged over replicates.

Breeding value estimation: When there is an observation on only a single phenotype, there is no independent information available on the mean and variance of the genotype, although \( P \) and \( P^2 \) provide point estimates. When phenotypes of a group of relatives each having the same relationship to an individual are available (e.g., progeny), statistics such as \( P \) and \( P^2 \), and var \( W \) can be used to predict its \( A_m \) and \( A_v \). Here \( P \) is the mean phenotype and \( P^2 \) is the mean \( P^2 \) of the relatives, var \( W = [n/(n - 1)](\langle P^2 \rangle - \langle P \rangle^2) \) is the within-family variance, and \( n \) is the number of relatives within the group. With large \( n \), var \( W \) becomes the main predictor of \( A_v \), but otherwise \( \langle P^2 \rangle \) contains additional information because animals with a high \( A_v \) have a higher probability of having a very high or low \( P \). This is similar to directional mass selection and the term \( \langle P^2 \rangle \) therefore plays an equivalent role to \( P^2 \). Although the Monte Carlo simulation was based on sires with half-sib progeny, the prediction of breeding values generalizes to any group of relatives with the same relationship. The multiple-regression equation can be represented as

### Table 3

Response to directional mass selection in \( A_m (\Delta A_m) \) and \( A_v (\Delta A_v) \) for different values of \( r_A \) and selected proportions comparing predictions [as prediction errors (predicted minus observed)] with observed responses obtained from Monte Carlo simulation (MC)

*Observed responses obtained from MC simulation: \( \sigma_{A_{m}}^2 = 0.3; \sigma_{A_{v}}^2 = 0.05; \sigma_{P}^2 = 0.7; \sigma_{\chi}^2 = \sigma_{A_{m}}^2 + \sigma_{A_{v}}^2 = 1.0. \)

*Predictions: MR3, multiple regressions on \( P, P^2 \), and \( P^3 \) (see Equation 5); MR2, multiple regressions on \( P \) and \( P^2 \) (see Equations 6 and 7); HZ, prediction based on Hill and Zhang (2004).
var W seems a logical choice to reduce both the non-normality of var W and the positive relationship between the mean and its sampling variance. When using ln(var W) instead of var W, the elements in the P- and G-matrices involving var W were transformed using a first-order Taylor series approximation (Lynch and Walsh 1998). The matrices $P_{ln}$ and $G_{ln}$ involving ln(var W) were calculated, respectively, as $P_{ln} = LPL$ and $G_{ln} = LG$, where $L = \text{diag}(1, 1, 1)$ and var W did not differ if $r A$ was computed for different values of var W using untransformed var W or ln(var W), as shown in Figure 3A for $r A = 0$. $A_{ln}$ is linear in standardized $P$ with a slope of $\frac{\sigma_{A}^2}{\sqrt{\text{var}(\hat{A}) + \frac{1}{4}(n-1)\sigma_{a}^2}} / n = 0.517$. The predicted $A_{ln}$ fitted well the expectation from Monte Carlo simulation ($R^2 > 0.99$) and the predictions using var W or ln(var W) did not differ if $r A = 0$.

Figure 3B shows that the relationship between $A_{ln}$ and var W is curvilinear for the case of 100 half-sib progeny when $r A = 0$. The predicted $A_{ln}$ using untransformed var W (MR linear) overestimated $A_{ln}$ for extreme values of var W, whereas predicted $A_{ln}$ using log-transformed var W (MR log) was curvilinear in var W and fitted well the expectation from Monte Carlo simulation ($R^2 > 0.99$).

As the bias in $A_{ln}$ was largest with extreme values of var W, the bias in $A_{ln}$ at 2 SD from the mean ln(var W) predicted by multiple regression using either var W or ln(var W) was computed for different values of $\sigma_{A}^2$ and numbers of progeny per sire (Table 4). Multiple regression on var W was seen to overestimate, but on ln(var W) to underestimate, $A_{ln}$. The bias using ln(var W) was negligible when the number of progeny was 100, but increased when the number of progeny was small (10) or large (10,000). The bias with var W was negligible with 10,000 progeny, as could be expected from the slow
convergence of a χ²-distribution to a normal distribution, and was small with a few progeny. Note that a higher degree of symmetry between the expected \( A \) at \(-2\) and \(2\) SD of the mean ln(var \( W \)) corresponded with a smaller bias in \( \hat{A} \) with ln(var \( W \)). The value of log-transformation of \( W \) thus depends on the number of progeny per sire.

**Response to directional selection on family mean:**
With the common procedure in livestock breeding to directionally select animals by truncation on the mean \( \bar{P} \) of relatives, e.g., progeny, information on the within-family variance (var \( W \)) is ignored. As for mass selection, if there is genetic heterogeneity of environmental variance, animals with a higher \( A \) would have a higher probability of selection when the selected proportion is \( <50\% \), diminishing as the number of relatives increases. If \( A_m \) and \( A_v \) are uncorrelated, the response in \( A_v \) is proportional to the selection differential \( \bar{P} \),

\[
\Delta A_v = b[(\bar{P})^2 - E\{(\bar{P})^2\}] = \text{bix var}(\bar{P}),
\]

where

\[
b = \frac{\text{cov}(A_v, (\bar{P})^2)}{\text{var}(\bar{P})} = \frac{\sigma^2_{A_v}}{\text{var}(\bar{P})} = \frac{2\sigma^2_{A_v} + 4\sigma_{A} \sigma_{A_v} (n-1)}{2\sigma^2_{A_v} + 6\sigma^2_{A} \sigma_{A_v} + (3+3\sigma_{A}^2)\sigma^2_{A_v}} \lim_{n \to \infty} \frac{b}{\sigma^2_{A_v}} = 0.
\]

There is therefore no selection pressure on \( A_v \) with an infinite number of relatives (Equation 11), as suggested by Hill and Zhang (2004) using a different argument.

Response in \( A_m \) and \( A_v \) with selection on \( \bar{P} \) can be generalized as

\[
\Delta A_m = \Delta A_v = b \left[ \frac{\bar{P}^2 - \mu}{\text{cov}(\bar{P}, \bar{P})} \right]_{\mu=0} = \frac{i\sigma_P}{\text{var}(\bar{P})}.
\]

To compute (12), var \( W \) was not included in the information vector \( x \) because selection is solely on \( \bar{P} \). For infinitely many relatives, Equation 12 can be rewritten as

\[
\Delta A_m = \Delta A_v = \frac{\sigma_P}{\sqrt{\text{var}(\bar{P})}},
\]

which is the corresponding standard breeders’ equation, and \( A_m \) is the corresponding standard breeders’ equation, and \( A_v = \frac{\sigma_P}{\sqrt{\text{var}(\bar{P})}} \), showing that response in \( A_v \) then becomes solely a correlated response to selection on \( \bar{P} \).

**Evaluation of predictions:** Table 5 shows predicted responses (Equation 12) in \( A_m \) and \( A_v \) when selecting on the mean of half-sib progeny \( \bar{P} \) in comparison to observed responses from Monte Carlo simulation. In general, these agreed well, although prediction errors were slightly higher when \( r_A \neq 0 \), especially with high selection intensity. As expected, the response in \( A_m \) increased with more progeny (higher accuracy of selection) and lower selected proportion (higher selection intensity). The response in \( A_v \) was small, becoming negligible with 100 progeny/sire when \( r_A = 0 \), but was, however, substantial when \( r_A \neq 0 \), basically as a correlated response to selection on the mean. Response in \( A_v \) increased nonlinearly with increasing selection intensity, similar to directional mass selection, but to a lesser extent. In conclusion, responses in \( A_m \) and \( A_v \) to selection on \( \bar{P} \) can be predicted accurately using multiple regression.
TABLE 5
Response to selection on mean of half-sib progeny ($\overline{P}$) in $A_m$ ($\Delta A_m$) and $A_s$ ($\Delta A_s$) for different values of $r_A$, different numbers of progeny/sire, and different selected proportions comparing predictions (MR) [as prediction errors (predicted minus observed)] with observed responses obtained from Monte Carlo simulation (MC)

$\sigma^2_{A_m} = 0.3; \sigma^2_{A_s} = 0.05; \sigma^2_E = 0.7; \sigma^2_v = \sigma^2_{A_m} + \sigma^2_E = 1.0.$

Defining a measure of heritability for environmental variance at the phenotypic level

Heritability ($h^2 = \sigma^2_A/\sigma^2_P$) is a central parameter in quantitative genetics (Falconer and Mackay 1966; Lynch and Walsh 1998). For standardization of results of analysis of genetic heterogeneity of environmental heterogeneity in field data and for making comparisons to “conventional” traits easier, it would be helpful to define a measure of heritability ($h^2_v$) for environmental variance at the phenotypic level. Heritability equals the regression coefficient of the breeding value $A$ on the phenotype $P$. Here we propose a definition of $h^2_v$, which equals the genetic variance in environmental variance as a proportion of the variance of $P^2$. This definition is equal to the regression of $A_s$ on $P^2$, where $b = \text{cov}(A_s, P^2)/\text{var}(P^2) = \sigma^2_A/\text{var}(P^2)$ and $\text{var}(P^2) = 2\sigma^4_P + 3\sigma^4_A$, and $h^2_v$ is therefore

$$h^2_v = \frac{\sigma^2_A}{2\sigma^4_P + 3\sigma^4_A}.$$ (13)

Alternatively, $h^2_v$ could be defined at the level of environmental variance, which equals one in Equation 1. On the basis of single phenotypic records, the environmental variance of a genotype is, however, not estimable. The measure of heritability in Equation 13 is directly related to single squared phenotypic records and as such is the natural analogy of the classical heritability of the mean ($h^2_{A_m}$), which can be used in prediction of response to mass selection when $r_A = 0$.

Under the assumption of $\sigma^2_{A_m} = 0$ and making use of Equation 13, Equation 9 can be greatly simplified when selecting on information of a group of relatives, for example, half-sib progeny. When $\sigma^2_{A_s} = 0$, var $W$ reduces to $(n/n - 1)\overline{P^2}$ because $E(P) = 0$, so the multiple regression for $\hat{A}_s$ can be simplified by regressing solely on $\overline{P^2}$. The accuracy of $\hat{A}_s$ can then be derived as

$$r_{A_s, A_s} = \frac{\sqrt{b_{A_s}^2}}{\sigma_{A_s}} = \frac{1}{\sigma_{A_s}} \sqrt{\frac{(1/2)n\sigma^2_A}{2\sigma^4_P + 3\sigma^4_A + (1/4)(n-1)\sigma^2_E}} \times \frac{1}{2} \times \sigma^2_A,$$

$$= \sqrt{\frac{(1/4)n\overline{h^2_v}}{1 + (1/4)(n-1)h^2_v}},$$ (14)

where $b_{A_s}$ and $g_{A_s}$ are columns of $B$ and $G$ corresponding to $A_s$. The resulting expression is exactly the same as that for accuracy of $A_m$ (Cameron 1997), except that $h^2$ is replaced by $h^2_v$. To investigate the effect of assuming $\sigma^2_{A_s} = 0$, the accuracy of $\hat{A}_s$ predicted with Equation 14 was compared to that predicted using Equation 9 and Monte Carlo simulation when $r_A = 0$ (Table 6). In general, accuracies were slightly underestimated by Equation 14, increasingly so with greater $\sigma^2_{A_m}$ ($\sigma^2_P = 1$), whereas the ones of Equation 9 were close to those from simulation. It seems that $h^2_v$ can be used as a first approximation in standard prediction equations when $r_A = 0$, but predictions should be interpreted with caution.

EXAMPLES OF CHANGING ENVIRONMENTAL VARIANCE BY SELECTION

In the previous section the focus was mainly on evaluating the goodness of fit of multiple-regression predictions with Monte Carlo simulation, but the results...
also show the effects of selection on environmental variance. For example, the response in $A_v$ with directional mass selection increased nonlinearly with increasing selection intensity (Table 3), and environmental variance increased unless $r_A < 0$. The response in $A_v$ was, however, negligible with directional selection on a half-sib progeny mean when $r_A = 0$ (Table 5), but was substantial when $r_A \neq 0$, due to a correlated response.

We now use the formulas (Equations 2, 3, and 9) to assess the effects of selection strategies aimed at changing the environmental variance, taking values of $\sigma^2_{A_v}$ between 0.01 and 0.10. These correspond to a low $k^2_e$ but are large relative to $\sigma^2_{B_v} = 0.7$, indicating a genetic coefficient of variation between 14 and 45%, higher than that for standard quantitative traits (Houle 1992). As expected, the accuracy of $\hat{A}_v$ increased with $\sigma^2_{A_v}$ (Table 7). The accuracy was low when using information only on own phenotype or a small number of progeny, but increased with number of relatives, especially with half-sib progeny, and when $r_A \neq 0$. With 1000 half-sib progeny, the accuracy was $>0.90$, unless $\sigma^2_{A_v} = 0.01$. Table 8 shows the predicted response in $A_v$ for directional, stabilizing, and disruptive selection based on phenotype (Equation 3, selection differentials from Table 2, neglecting the terms involving $P^3$) and for directional downward selection on $\hat{A}_v$ based on 100 half-sib progeny assuming $r_A = 0$ (calculated as $\Delta A_v = n \hat{r}_{A_v} \sigma^2_{A_v}$, where $\hat{r}_{A_v} = \sqrt{b_{A_v} \hat{g}_{A_v}}/\sigma_{A_v}$). Predictions were close to observed responses in Monte Carlo simulation. For all selection strategies, responses in $A_v$ increased with $\sigma^2_{A_v}$ due to a higher accuracy and a higher genetic variance in itself.

With directional and disruptive selection on phenotype, the predicted response in $A_v$ was positive and environmental variance increased substantially and nonlinearly with selection intensity. Disruptive selection gave a slightly larger response because the selection intensity in each tail of the distribution of $P$ was higher. With stabilizing selection on phenotype, the response in $A_v$ was negative but small, even when the selection was intense because selection differentials remain small and were nearly constant (Table 2). With directional downward

$\sigma^2_{A_v} = 0.3$; $\sigma^2_{B_v} = 0.7$; $\sigma^2_v = \sigma^2_{A_v} + \sigma^2_{B_v} = 1.0$.
selection on $\hat{A}_v$ based on 100 half-sib progeny, response in $\hat{A}_v$ was negative and environmental variance decreased substantially, which in an agricultural context would imply increased uniformity of end product. Responses increased linearly with selection intensity and became large, especially with $\sigma^2_{\hat{A}_v} \approx 0.05$. When the best 5% of the sires are selected on $\hat{A}_v$ and dams are selected at random with $\sigma^2_{\hat{A}_v} = 0.05$, the environmental variance would be 0.554 in the next generation, which is only 79.1% of that in the current generation! In conclusion, a large number of relatives is necessary to predict breeding values and selection responses in the current generation. A multiple-regression framework has been developed to predict breeding values and selection responses in mean and variance for mass selection and selection between families in the presence of genetic heterogeneity of environmental variance. The model of Hill and Zhang (2004) has been refined for directional mass selection and extended to stabilizing and disruptive selection based on phenotype and on between-family selection. The phenotypic variance increases nonlinearly with selection intensity under directional mass selection when $r_1 = 0$. It increases even more with disruptive selection, but decreases only slightly with stabilizing selection, which is in agreement with results of Gavrilets and Hastings (1994) and Wagner et al. (1997). With selection on family mean, phenotypic variance is expected to change little unless $r_1 \neq 0$, but with selection on within-family variance, response in phenotypic variance may be large providing $\sigma^2_{\hat{A}_v} > 0$, even though a large number of relatives is necessary to estimate $\hat{A}_v$ accurately.

**Methodology:** Comparison of genetic models: Different genetic models to account for genetic heterogeneity of environmental variance appear in the literature, basically either additive effects both at the level of the mean and at the level of the environmental variance (Hill and Zhang 2004; Zhang and Hill 2005; this study) or additive effects on the mean and an exponential model for the environmental variance (SanCristobal-Gaudy et al. 1998, 2001; Sorensen and Waagepetersen 2003; Ros et al. 2004). In the exponential model

$$P = \mu + A_m + \chi \exp \left( \ln(\sigma^2_{E,exp}) + A_{e,exp} \right),$$

where $\sigma^2_{E,exp}$ is the environmental variance when $A_{e,exp} = 0$, and $A_{e,exp}$ is the individual’s breeding value for environmental variance in the exponential model, such that environmental variances are multiplicative on the observed scale and additive on a log-scale. (Note that $\ln(\sigma^2_{E,exp}) = \eta$ in the notation of SanCristobal-Gaudy et al. 1998.) The distribution of true variances (not variance estimates) is unknown in practice and cannot help in guiding whether the additive model or the exponential model better reflects the real world. Clearly, each model has specific (dis)advantages. The exponential model has tractable properties so it is easier

**DISCUSSION**

A multiple-regression framework has been developed to predict breeding values and selection responses in mean and variance for mass selection and selection between families in the presence of genetic heterogeneity of environmental variance. The model of Hill and Zhang (2004) has been refined for directional mass selection and extended to stabilizing and disruptive selection based on phenotype and to between-family selection. The phenotypic variance increases nonlinearly with selection intensity under directional mass selection when $r_1 = 0$. It increases even more with disruptive selection, but decreases only slightly with stabilizing selection, which is in agreement with results of Gavrilets and Hastings (1994) and Wagner et al. (1997). With selection on family mean, phenotypic variance is expected to change little unless $r_1 \neq 0$, but with selection on within-family variance, response in phenotypic variance may be large providing $\sigma^2_{\hat{A}_v} > 0$, even though a large number of relatives is necessary to estimate $\hat{A}_v$ accurately.
to use in data analysis; for example, the environmental variance
can never become negative, whereas in the
additive model the term $\sqrt{\sigma^2_A + \sigma^2_e}$ is defined only when
$\sigma^2_A + \sigma^2_e > 0$. The additive model, however, fits nicely in
quantitative genetic theory, leading to better properties
for deterministic predictions of selection response. A
disadvantage of the exponential model is that the
average environmental variance in the population is
$\sigma^2_e = \sigma^2_{e,\exp} \exp\left(\frac{1}{2} \sigma^2_{A,\exp}\right)$, so there is no full separation of
the mean environmental variance and the genetic variance in environmental variance, and $\sigma^2_{A,\exp}$ has to be
known to interpret $\sigma^2_{e,\exp}$.

Fortunately, the models are sufficiently similar that
their genetic parameters can be interconverted. The
breeding values for environmental variance can be
converted by equating the expectations of the second
central moments of the environmental effects (see
APPENDIX B):

$$A_e = \sigma^2_{e,\exp} \exp(\Lambda_{e,\exp}) - \sigma^2_e$$  (16)

[a first-order Taylor series approximation of Equation
16 is $A_e = \Lambda_{e,\exp} \times \sigma^2_{e,\exp} + (\sigma^2_{e,\exp} - \sigma^2_e)$, illustrating the
factor $\sigma^2_{e,\exp}$ between breeding values and the correction
for the difference between $\sigma^2_{e,\exp}$ and $\sigma^2_e$.]

The genetic variances can be converted by equating the
fourth central moments of the environmental effects:

$$\sigma^4_{A} = \sigma^4_{e,\exp} \exp(2\sigma^2_{A,\exp}) - \sigma^4_e$$  (17)

(a first-order Taylor series approximation of Equation
17 is $\sigma^4_{A} = \sigma^4_{e,\exp} \times \sigma^4_{A,\exp} + (\sigma^4_{e,\exp} - \sigma^4_e)$, showing a
factor $\sigma^4_{e,\exp}$ between genetic variances and a correction
for the difference between $\sigma^4_{e,\exp}$ and $\sigma^4_e$]. Thus results
obtained using the exponential model in data analysis
could be converted using Equations 16 and 17 to the
additive model and the deterministic equations derived
in this study used to predict selection responses.

Gavrilets and Hastings (1994) and Wagner et al.
(1997) adopted slightly different multiplicative models
to deal with genetic heterogeneity of environmental variance,
but these are in essence very similar to the
exponential model.

Multiple-regression framework: In this study, a multiple-
regression framework was used to predict breeding
values and selection responses. Prediction equations
were derived for incorporating phenotypic information
of only one type, individual or family statistics, but the
method can easily be extended to situations where pheno-
typic information is available from different kinds of
relatives. For the common situation of optimal weighting
of own performance and family information, most of
the necessary elements in the prediction equation either
have been derived here or can be derived straightforwardly
using the same methods. Furthermore, the re-
gression structure enables prediction of responses in
mean and variance with different selection strategies
using the classical selection index theory and extension to
give optimal changes in mean and variance via a selec-
tion index (Hazel 1943). The framework presented can
be used only for prediction of selection response after
one generation of selection; due to buildup of gametic
disequilibrium, genetic variance would decrease
with direction selection, lowering selection responses
(Bulmer 1971). Furthermore, gametic phase disequilibrium
induces an unfavorable covariance between the additive
genetic effects for mean and environmental variance,
counteracting desired changes in mean and variance
(Hill and Zhang 2004). Inclusion of the Bulmer effect
was beyond the scope of this article, but could be im-
plemented (Hill and Zhang 2004, 2005).

In the multiple-regression framework fixed effects are
assumed to be known without error, but in practice they
are estimated from the data, thereby reducing accuracy
and selection response. Therefore, results in this study
should be interpreted using an effective number of observ-
ations, which is lower than the actual number of observa-
tions. To predict breeding values in the presence of fixed
effects on mean (e.g., herd effect) and variance (e.g., hetero-
genesis of variance between herds, environments with
different stress levels), a model with genetically structured
environmental variance can be used (SanCristobal-
Gauudy et al. 1998; Sorensen and Waagepetersen
2003). Modeling of environmental heterogeneity of
variance (e.g., between herds) has been reviewed by
Foulley and Quaas (1995) and Hill (2004). To predict
selection responses with genetic heterogeneity of envi-
ronmental variance in environments differing in mean
environmental variance (e.g., herds, stress levels), the
present framework can be used by adjusting $\sigma^2_e$.

A disadvantage of the multiple-regression framework is
that it relies on the assumption that the explanatory
variables ($x$) are linearly related to the dependent
variables ($y$), which is ensured when $x$ and $y$ are bivariate
normally distributed. As a consequence, results may not
be robust against deviations from normality, particularly
when higher-order terms such as $x^3$ are included in
predictions. The multiple-regression framework was,
however, robust against small deviations from normal-
ity induced by genetic heterogeneity of environmental variance.
SanCristobal-Gauudy et al. (1998) and
Sorensen and Waagepetersen (2003) also assumed
multivariate normality in predictions of selection re-
sponses, but their approaches were more flexible in
allowing for other distributions. Their approaches were
not very different from those in this study, but some
expressions were much more complex due to the use of
the exponential model.

Multiple-regression methods would be useful to study
the evolution of phenotypic variance in natural popula-
tions, to further develop analyses of Zhang and Hill
(2005). Selection for reduced environmental variance
could result in environmental canalization, a phenom-
enon of long-standing interest (e.g., Waddington
1942, 1960; reviews in Scharloo 1991, Debat and David...

*a Models included permanent environmental variance; environmental variance was taken from their model 1 estimates.
*b Equation 17: $\sigma^2_A = \sigma^2_{E,\text{exp}} \exp(2\sigma^2_{A,\text{exp}}) - \sigma^2_E$.
*c $h^2_E = \sigma^2_A / (2\sigma^2_E + 3\sigma^2_A)$ = heritability of environmental variance.
*d $\text{GCV}_E = \sigma_A / \sigma_E$, a measure of evolvability (Houle 1992).

2001, and Flatt 2005). On the basis of our predictions, stabilizing selection cannot cause environmental canalization of traits within a few generations, but may do so eventually. With long-term canalizing selection, the question arises whether the limit of environmental variance is zero, whereas most quantitative traits in nature under stabilizing selection still exhibit environmental variance (e.g., Wagner et al. 1997). We know little about how levels of environmental variation are determined and maintained in the face of stabilizing selection. Different mechanisms have been proposed (e.g., Wagner et al. 1997), such as introducing a cost for homogeneity or canalization (Zhang and Hill 2005). To further investigate long-term effects of natural selection on environmental variance, the current framework can be extended to include the effects of gametic phase disequilibrium, inbreeding, and mutation, analogous to effects of selection on the mean of traits.

Evidence for genetic heterogeneity of environmental variance: Although the tools for evaluating breeding strategies to change the mean and the size of environmental variance are now available, the whole exercise would just be a theoretical game if $\sigma^2_A = 0$. As reviewed in the Introduction, there is empirical evidence that genotypes differ in environmental variance, but it is not abundant. To compare results of different studies analyzing field data we use Equation 17, because some are based on the exponential genetic model (SanCristoba-Gaudy et al. 1998, 2001; Sorensen and Waagepetersen 2003; Ros et al. 2004) and some on the additive genetic model (Rowe et al. 2006). The measure of heritability ($h^2_E$) developed in this study (Equation 13) and the genetic coefficient of variation for environmental variance $\text{GCV}_E = \sigma_A / \mu = \sigma_A / \sigma_E^2$, denoted “evolvability” (Houle 1992), are used to compare results from different studies (Table 9). Heritabilities of environmental variance were low, in the range 0.02–0.05 as used in this study, and GCV_E’s were large, in the range of 0.30–0.58 (excluding 0). Note that GCV_E^2 is close to $\sigma^2_{A,\text{exp}}$. The low values of $h^2_E$ show that a large amount of information is necessary to estimate $\hat{A}_e$ accurately, but the high values of GCV_E show that there is substantial opportunity for genetic change.

Other evidence of the existence of genetic heterogeneity of environmental variance can come from selection experiments. With genetic heterogeneity of environmental variance, environmental variance would decrease with stabilizing selection and increase with disruptive selection. In most studies (e.g., Rendel et al. 1966; Cardin and Minvielle 1986), however, only changes in phenotypic variance are reported, which are not separated into changes in genetic and environmental variance. Interpretation of any selection experiment is complicated by possible changes in genetic variance due to gene frequency change, which cannot be predicted from simple base population parameters. Under infinitesimal model assumptions, effects of gene frequency change can be ignored and those due to gametic phase disequilibrium can be predicted. Due to negative gametic phase disequilibrium, genetic variance is expected to decrease with stabilizing selection and increase with disruptive selection (Bulmer 1971). In agreement with this expectation, Kaufman et al. (1977) found substantial decreases in genetic and environmental variance with stabilizing selection in T. castaneum and Scharloo et al. (1972) observed substantial increases in genetic and environmental variance with disruptive selection in D. melanogaster, indicating a substantial genetic variance in environmental variance. Sorensen and Hill (1983), however, found large increases only in genetic variance with disruptive selection in D. melanogaster.
Even though some studies analyzing field data or selection experiments show existence of genetic heterogeneity of environmental variance, it could still be due to statistical artifacts, e.g., due to confounding genetic and environmental effects on variance or violation of the infinitesimal model assumption. If genetic heterogeneity of environmental variance is a truly biological phenomenon, it could be due to scaling, genetic variance in environmental sensitivity, or a combination of both. Traits seem to have a rather constant CV, even when the mean changes dramatically due to selection (Hill and Bünger 2004). A constant CV would require a correlation of unity between mean and standard deviation, which has not been found in analysis of field data (Sorensen and Waagepetersen 2003; Ros et al. 2004; Rowe et al. 2006). Genetic heterogeneity of environmental variance can arise from genetic differences in environmental sensitivity (Falconer and Mackay 1996; Lynch and Walsh 1998). When genotypes perform under variable environmental conditions, which are unknown to the researcher, genetic differences in response to environmental conditions may be observed as genetic heterogeneity of environmental variance.

Genetic heterogeneity of environmental variance is a complicated phenomenon and there is not yet abundant evidence of its existence. The results in this study may help in understanding the consequences of genetic heterogeneity of environmental variance on phenotypes and the methods can help in designing selection experiments and in evaluating breeding strategies or the effects of natural selection that change both the mean and the variance. Genetic heterogeneity of environmental variance may indeed be exploited to breed more "robust" or "stable" genotypes.

H.M. thanks Johan van Arendonk, Bart Ducro, and Roel Veerkamp for valuable comments on earlier versions of the manuscript. We thank Ian White for statistical advice. European Animal Disease Genomics Network of Excellence for Animal Health and Food Safety is acknowledged for financial support to a visit of H.M. to Edinburgh and the Biotechnology and Biological Sciences Research Council for research support to W.G.H.

APPENDIX A: DERIVATION OF ELEMENTS IN THE P- AND G-MATRICES

Selection on a single phenotype: The elements in the \( P \) - and \( G \)-matrices were derived as follows, using the Roman \( E \) to denote expectation and the italic \( E \) to denote the environmental deviation \( E = \chi \sigma_E^2 + \alpha \), and noting that \( E(\chi^2) = 1 \):

\[
E(P) = 0, \quad E(P^2) = \sigma_E^2.
\]

\[
E(P^3) = E(A_m^3 + 3A_m^2E + 3A_mE^2 + E^3) = 0 + 0 + 3E \{ A_m(\sigma_E^2 + \alpha) \} + 0 = 3\text{cov}_{\text{Am}},
\]

\[
E(P^4) = E(A_m^4 + 4A_m^3E + 6A_m^2E^2 + 4A_mE^3 + E^4) = 3\sigma_P^4 + 3\sigma_E^2,
\]

\[
E(P^5) = E(A_m^5 + 5A_m^4E + 10A_m^3E^2 + 10A_mE^3 + 5A_mE^4 + E^5) = 30\sigma_P^2\text{cov}_{\text{Am}},
\]

\[
E(P^6) = E(A_m^6 + 6A_m^5E + 15A_m^4E^2 + 20A_m^3E^3 + 15A_mE^4 + 6AE^5 + E^6)
= 15\sigma_P^6 + 45\sigma_P^4\sigma_E^2 + 90\text{cov}_{\text{Am}}^2 + 45\sigma_P^2\sigma_E^2.
\]

\[
\text{var}(P) = E(P^2) - (E(P))^2, \quad \text{var}(P^2) = E(P^4) - (E(P^2))^2,
\]

\[
\text{cov}(P, P^2) = E(P^3) - E(P)E(P^2), \quad \text{cov}(P, P^3) = E(P^4) - E(P^2)E(P^2),
\]

\[
\text{var}(P^2, A_m) = \sigma_{A_m}^2,
\]

\[
\text{cov}(P^2, A_m) = \text{cov}(A_m^2 + 2A_mE + E^2, A_m) = 0 + 0 + \text{cov}(E^2, A_m) = \text{cov}_{A_m},
\]

\[
\text{cov}(P^2, A_m) = \text{cov}(A_m^2 + 3A_mE^2 + E^3, A_m)
= \text{cov}(A_m^3, A_m) + \text{cov}(3A_mE^2, A_m) = 3\sigma_{A_m}^4 + 3\sigma_{A_m}^2\sigma_E^2 = 3\sigma_P^2\sigma_E^2.
\]

Similarly \( \text{cov}(P, A) = \text{cov}_{A_m}, \text{cov}(P^2, A) = \sigma_{A_m}^2 \), and \( \text{cov}(P^3, A) = 3\sigma_{Pm}^2\text{cov}_{\text{Am}} \).

Selection based on a group of relatives:

\[
\text{var}(P) = \left( \sigma_P^2 + a_m(n-1)\sigma_{A_m}^2 \right) / n
\]

\[
\text{cov}(P, P^2) = \left[ n \text{cov}(P_k, P_k^2) + n(n-1) \{ \text{cov}(P_k, P_k^2) + 2\text{cov}(P_k, P_kP_l) \} \right] / n^3
= \left[ \{ 3 + 3a_m(n-1) \} \text{cov}_{\text{Am}} \right] / n^2
\]

\[
\text{var}(P^2) = \left[ n \text{var}(P_k^2) + n(n-1) \{ \text{cov}(P_k^2, P_k^2) + 4\text{cov}(P_k^2, P_kP_l) + 2\text{cov}(P_kP_l, P_kP_l) \} \right] / n^4
= 2 \left[ \left( \sigma_P^2 + a_m(n-1)\sigma_{A_m}^2 \right) / n \right]^2 + \left[ \{ 3 + 3a_m(n-1) \} \sigma_{A_m}^2 \right] / n^3
\]

\[
\text{var}(P^2) = \left[ n \text{var}(P_k^2) + n(n-1)\text{cov}(P_k^2, P_l^2) \right] / n^2 = \left[ 2\sigma_P^4 + 3\sigma_E^2 \right] + (n-1) \left[ 2\sigma_P^4 \sigma_{A_m}^2 + a_m\alpha \right] / n
\]

\[
\text{cov}(P, P^2) = \left[ n \text{cov}(P_k, P_k^2) + n(n-1)\text{cov}(P_k, P_l^2) \right] / n^2 = \left[ 3 + a_m(n-1) \right] \text{cov}_{\text{Am}} / n
\]

\[
\text{cov}(P, \text{var}) = \left[ n(n-1) \right] \times \left[ \text{cov}(P, P^2) - \text{cov}(P, (P)^2) \right] = \left[ 3 + a_m(n-3) \right] \text{cov}_{\text{Am}} / n
\]
\[
\text{cov}((\bar{P})^2, \overline{P^2}) = \left[ \text{var}(P_k^2) + (n-1)\{ \text{cov}(P_k^2, P_l^2) + 2 \text{cov}(P_k^2, P_l P_m) \} + (n^2 - 3n + 2) \text{cov}(P_k^2, P_l P_m) \} / n^2
\]
\[
= \left\{ 2\sigma_p^4 + 3\sigma_h^4 \right\} + \left\{ 2\sigma_h^2(n-1)^2\sigma_h^4 \right\} + a_w(n-1)\left\{ \sigma_h^2 + 4\sigma_p^2\sigma_h^4 \right\} / n^2
\]

\[
\text{cov}((\bar{P})^2, \text{var} W) = [n/n - 1] \times \left[ \text{cov}((\bar{P})^2, \overline{P^2}) - \text{var}((\bar{P})^2) \right] = \left\{ 3 + a_w(n-3) \right\} \sigma_h^2 / n^2
\]

\[
\text{var} \text{var} W = \text{var} \left( \left( n/n - 1 \right) \times \left( \overline{P^2} - (\bar{P})^2 \right) \right) = [n/n - 1^2 \left[ \text{var} \overline{P^2} - 2 \text{cov} (\overline{P^2}, (\bar{P})^2) + \text{var} ((\bar{P})^2) \right]
\]
\[
= \left( \left\{ 2 \left( \sigma_p^4 - a_w \sigma_h^4 \right)^2 \right\} / (n - 1) \right) + \left( \left\{ 3(n - 1) + a_w(n^2 - 2n + 3) \right\} \sigma_h^2 \right) / (n(n - 1))
\]

where \( k, l, m, \) and \( n \) are different relatives within the family.

\[
\text{cov} (\bar{P}, A_{m,j}) = a_j \sigma_h^2
\]

\[
\text{cov}((\bar{P})^2, A_{m,j}) = [n \text{cov}(P_k^2, A_{m,j}) + n(n-1)\text{cov}(P_l P_j, A_{m,j})] / n^2 = a_j \text{cov}_{\lambda m} / n
\]

\[
\text{cov} (\text{var} W, A_{m,j}) = \text{cov} \left( \left[ n/n - 1 \right] \left( \overline{P^2} - (\bar{P})^2 \right), A_{m,j} \right) = a_j \text{cov}_{\lambda m}
\]

and similarly \( \text{cov} (\bar{P}, A_{c,j}) = a_j \text{cov}_{\lambda c}, \text{cov}((\bar{P})^2, A_{c,j}) = a_j \sigma_h^2 / n, \text{and cov} (\text{var} W, A_{c,j}) = a_j \sigma_h^2. \)

**APPENDIX B: SIMILARITIES BETWEEN EXPONENTIAL AND ADDITIVE GENETIC MODELS**

The breeding values for environmental variance were converted from the exponential model (Equation 15) to the additive model (Equation 1) by equating the second central moments of the environmental effects of both models resulting in Equation 16:

\[
E(E^2) = E \left( E^2_{\text{exp}} \right)
\]

\[
\sigma^2_E + A_e = \exp \left( \ln \sigma^2_{E,\text{exp}} + A_{e,\text{exp}} \right)
\]

\[
A_e = \exp \left( \ln \sigma^2_{E,\text{exp}} + A_{e,\text{exp}} \right) - \sigma^2_E.
\]

The genetic variance in environmental variance was converted from the exponential model to the additive model by equating the fourth central moments of the environmental effects of both models resulting in Equation 17 (e.g., Stuart and Ord 1994):

\[
E(E^4) = E \left( E^4_{\text{exp}} \right)
\]

\[
3E \left( \left( \sqrt{\sigma^2_E + A_e} \right)^4 \right) = 3E \left( \left( \exp \left( \frac{1}{2} \ln \sigma^2_{E,\text{exp}} + \frac{1}{2} A_{e,\text{exp}} \right) \right)^4 \right)
\]

\[
\sigma^4_E + \sigma^2_h = \sigma^4_{E,\text{exp}} \exp (2 \sigma^2_{h,\text{exp}})
\]

\[
\sigma^2_h = \sigma^4_{E,\text{exp}} \exp (2 \sigma^2_{h,\text{exp}}) - \sigma^4_E.
\]
